#### Abstract

Many landscape, limnological, and ecological factors synergistically affect the mercury cycle and subsequently influence total mercury ( THg ) concentrations in fish. In Chapter 1, the associations between watershed and lake scale characteristics with THg in piscivorous fish are examined. ArcGIS was used to delineate the waterbody catchment area and extract waterbody catchment characteristics for 243 of northern Ontario's lakes. Walleye (Sander vitreus, $\mathrm{n}=121$ lakes), lake trout (Salvelinus namaycush, $\mathrm{n}=60$ lakes), brook trout (Salvelinus fontinalis, $\mathrm{n}=18$ lakes), northern pike (Esox lucius, $\mathrm{n}=107$ lakes), and smallmouth bass (Micropterus dolomieu, $\mathrm{n}=37$ lakes) were standardized to the mean length of the populations by using power-series regressions. Multivariate analysis (nonmetric multidimensional scaling) and univariate analysis were used to determine the associations between total mercury concentrations in fish and watershed scale and lake scale variables. Watershed and lake chemistry characteristics poorly described the variability in THg concentrations. Forest harvesting and natural disturbance were not associated with fish mercury concentrations.

In Chapter 2, the relationship between walleye (Sander vitreus) growth rates and mercury concentrations was evaluated. The von Bertalanffy growth model was used to standardize the age of walleye to the mean total length. Walleye populations with slower growth rates had higher THg concentrations ( $\mathrm{r}^{2}=0.333, p<0.001$ ), suggestive of growth efficiency. Moreover, abundance of walleyes was associated with the growth rate ( $r^{2}$ $=0.136, p<0.0001$ ).

Concentrations of THg in piscivorous fish are attributed to physical, chemical, and ecological characteristics of lakes. It is likely that lake ecology exerts the strongest influence on high mercury concentrations in piscivorous species, masking the effect from from watershed disturbance.

## Lay Summary

This thesis contributes to the body of research addressing mercury as a dangerous global pollutant as well as a harmful fish contaminant. In Ontario, mercury accounts for $86.2 \%$ of consumption restrictions from inland water bodies ${ }^{1}$. In the Boreal Shield where forest harvesting is a major landscape-scale disturbance, the connection between forest harvesting and mercury contamination of sport-fish is not well defined and requires further assessment. Forest vegetation and soil sequester and retain atmospheric and naturally occurring geologic mercury within their watersheds for long periods of time. Changes in watershed hydrology can cycle terrestrial mercury to the aquatic environment. While certain variables are known to influence the production and accumulation of MeHg in aquatic ecosystems, investigation of the relative importance of watershed and lake characteristics that simultaneously influence mercury contamination in freshwater fish is lacking. This paper specifically addresses the associations between lake chemistry, spatial characteristics of the lake and waterbody catchment environment, and biological relationships between the terrestrial and aquatic ecosystem in order to gain a better understanding of mercury contamination of sport-fish in connection with forest harvesting activities.

## Acknowledgements

Above all, I would like to acknowledge Dr. Rob Mackereth for his continuous support and advice. I am very grateful to have had the opportunity to be a graduate student at the Centre for Northern Forest Ecosystems Research and to have met so many fantastic people over the years! In particular, I am extremely thankful for Darren McCormick, my mentor in GIS. I would like to thank my committee members, Dr. Peter Lee and Dr. Greg Pyle, for their advice and improvements to this project. A special thanks to Satyendra Bhasvar, Andrew Paterson, and Chris Mahon who helped me obtain copious amounts of fish mercury and lake chemistry data from the Ministry of the Environment database. A further special thanks to Kim Armstrong and Jeff Amos who helped facilitate this project by providing me with the Ministry of Natural Resources Broadscale Fisheries Data. I would like to thank Larry Watkins, who provided me with the provincial forensic forestry layers. I would like to thank James Cross, who helped me with obtaining outputs from the Historical Climate Analysis Tool. I would like to thank Dr. Ogle, Northland College, who helped me with R-scripting. Lastly, many unmentioned individuals who were involved in the MNR's Broadscale Fisheries Program and MOE's Provincial Sport Fish Contaminant Monitoring Program also deserve my appreciation since all their hard work in the field and the lab formed the roots of this project.

## 0. General Introduction

## Mercury as a Global Pollutant

Mercury exists in the global environment either from naturally occurring geological sources or as a result of human activities. Even as the direct toxicity of mercury has been known for thousands of years, humans have only known of the trophic transfer of mercury and other biocontaminants since the 1960's (Takizawa 1979). Our understanding of mercury's behaviour in the environment was initiated by human tragedies that were linked to point-source discharges of mercury (Munthe et al. 2007).

The most severe case of mercury contamination from consumption of contaminated fish occurred in Minamata Bay, Japan in the late 1950's where 2252 people were severely affected (Harada 1995). The point-source pollution came from an acetaldehyde manufacturing plant, which discharged 456 tons of mercury into Minamata Bay between 1932 and 1968 (Díez 2008). This disastrous event was the first case of mercury poisoning caused by food chain transfer of pollutants that led to very high concentrations of mercury in fish and shellfish (Harada 1995). This awakened the world to the dangers of mercury and the threat of mercury contamination in fish and other aquatic biota.

Soon after the Minamata tragedy, direct discharges of mercury were virtually eliminated from Ontario's major industrial polluters (Mohapatra et al. 2007; OMOE 2011). However, decades of use and inappropriate disposal of mercury have left their mark on the fish and wildlife of environmental systems. For example, the English-Wabigoon river system (located near Dryden, Ontario) has been declared contaminated since 1970. Dryden's chlor-alkali industry used the mercury-cell cathode for manufacturing caustic soda and was a major discharger of mercury directly to the aquatic environment. Between 1962 and 1970, approximately 10 metric tonnes of inorganic mercury were released in the effluent water of the chlor-alkali plant (Kinghorn et al. 2007). Mercury concentrations in walleye (Sander vitreus) from Clay Lake in 1970 exceeded 15 ppm w.w. (standardized total length of 500 mm ) (Parks and Hamilton 1987). All fish species from the English-Wabigoon river system were considered unfit for human consumption due to severe mercury contamination. The contamination of fish of the EnglishWabigoon system resulted in the closure of the sustenance, commercial, and recreational fisheries in May of 1970 (Kinghorn et al. 2007). Over the past few decades, a slow recovery
from the environmental damage has been continually monitored and the levels of mercury have declined in the biota whereby certain sizes and species of fish are now able to be consumed (Kinghorn et al. 2007; OMOE 2011).

Around the mid 1980's, global studies found the occurrence of mercury contaminated fish in remote locations lacking substantive sources of local mercury inputs from anthropogenic or geologic sources (USGS 1995). Mercury was soon recognized as a "global pollutant" (Schroeder and Munthe 1998; Fitzgerald et al. 1998). The source of mercury pollution to these remote ecosystems was determined to be atmospheric fallout. Mercury's long atmospheric residence time enables the elemental form to be transported for tens of thousands of kilometres in the troposphere from its point-source (Grigal 2002). By the mid 1990's, mercury gained worldwide attention from scientists and resource managers as it became known as the most widespread contaminant of aquatic ecosystems (USGS 2010).

## Mercury Emissions

Global atmospheric emissions of mercury have greatly increased since the industrial revolution. The 2005 estimate of mercury emissions from human sources was estimated to be approximately 1930 tonnes, whereby Asia is the leading polluter accountable for about twothirds of this amount (UNEP 2008). The United States of America and India, as the second and third largest emitters respectively, equate merely to one-third of China's emissions when combined total emissions are compared (UNEP 2008).

The primary sources of atmospheric mercury from anthropogenic sources are fossil fuel combustion, mining activities, and industrial processes that smelt ores or produce cement (UNEP 2008). The largest single source of anthropogenic mercury emissions is the combustion of fossil fuels and China is by far the largest emitter, mainly due to coal combustion, compared to all other countries (Seigneur et al. 2003; Pacyna et al. 2006; UNEP 2008). Mercury pollution from coal is a result of the enormous amounts of coal being consumed rather than from the levels of mercury in coal which varies according to geologic origin from 0.01 to 1.5 ppm (Pacyna et al. 2006; UNEP 2008).

Secondary anthropogenic sources of mercury are released from industrial processes or from mercury-containing consumer products. Artisanal or small-scale gold mining and the chloralkali industry are major industrial sources of secondary anthropogenic mercury to the
environment (UNEP 2008). A considerable amount of pollution is also from mercury's widespread occurrence in consumer products including common household items (batteries, paint, switches, thermometers, blood-pressure gauges, fluorescent lights), dental amalgam, pesticides, fungicides, medicines, and cosmetics (UNEP 2008). Until mercury-containing products are phased out of the global marketplace, mercury continues to be widely used and released into the environment regardless of the known potential dangers and health risks. In Canada, the use and improper disposal of products containing mercury currently represents about 27\% of Canada's total emissions (Canada Gazette 2011).

Since the 1970 's, Canada has taken aggressive action and has reduced its industrial mercury emissions by approximately $90 \%$ and as a result is only responsible for approximately $1.42 \%$ of the total global mercury emissions (Canada Gazette 2011). Canada accomplished this decrease by implementing regulations, pollution prevention plans, and Canada-wide standards for mercury emissions from waste incineration, base metal smelting, and coal-fired electric power generating stations (Canada Gazette 2011).

## Natural Geologic Sources of Mercury

Mercury is released into the global environment naturally by the weathering of mercurycontaining rocks and soils, volcanic eruptions, and geothermic activity (UNEP 2008). These natural sources of mercury account for one third to a half of mercury emissions to the atmosphere (UNEP 2008).

Mercury occurs naturally in a number of geological formations but rich geological deposits of mercury are most often found in the form of cinnabar (red mineral or ore composed of mercury sulphide: HgS ) or metacinnabar (Jonasson and Boyle 1971). The mercury content in cinnabar can reach concentrations as high as $86 \%$ (Jonasson and Boyle 1971). However, in Canada mercuriferous belts rich in cinnabar are generally not found east of the Rocky Mountains (National Research Council Canada 1979). None the less, natural background concentrations of mercury may be influenced by widespread geological formations that contain varying levels of mercury (Rasmussen et al. 1998). Mercury deposits occur in all types of rocks, but sedimentary rocks of the Palaeozoic to Recent age contain greater concentrations of mercury (Jonasson and Boyle 1972). The average mercury content is much higher in shales ( 0.4 ppm Hg ) compared to sandstones and limestones ( 0.03 ppm Hg ) and granites ( 0.08 ppm Hg ) (Goldwater 1972).

Studies by the Geological Survey of Canada (GSC) found some of the highest sediment mercury values in Ontario's Lakes southwest of Thunder Bay in an area underlain by shale (Friske and Coker 1995).

Elevated mercury levels in bedrock are associated with mineralization (Jonasson and Boyle 1972). High soil mercury levels have been reported in Quebec and Ontario near areas of known gold, copper, or zinc mineralization (Environment Canada 1979). The Red Lake area, which is situated near a rich gold deposit, has mercury concentrations in the rock cores twice as high as in cores from adjacent non-mineralized regions of Northwestern Ontario (Bishop and Neary 1976). However, mercury levels in fish from the Red Lake area have not been noticeably higher than those from other off-system lakes from different geological formations (Bishop and Neary 1976).

Research across Canada has shown that physical and chemical weathering and erosion of bedrock, glacial deposits, and soil enriched in mercury ultimately increases the mercury load in lakes and streams (Jonasson and Boyle 1972; Hornbrook and Jonasson 1971; Rasmussen et al. 1998; Friske and Coker 1995). The weathering of local geology may be a leading contributor to the elevated mercury levels in the environment but distinguishing the relative contribution of mercury from natural sources is a major challenge. However, natural geologic sources of mercury alone are insufficient to explain the increased number of lake sediment and peat profiles with substantial increases in mercury levels during the last century (Engstrom et al. 2007; Fitzgerald et al. 1998).

## The Mercury Cycle

The environmental mercury cycle has four strongly interconnected realms: atmospheric, terrestrial, aquatic, and biotic (Wiener et al. 2003). Mercury is reasonably reactive in the environment and cycles readily among the four compartments as it can exist naturally in the solid, liquid or gas physical state (Ullrich et al. 2001; Wiener et al. 2003). Mercury has three valence states $\left(\mathrm{Hg}^{0}, \mathrm{Hg}^{1+}\right.$, and $\left.\mathrm{Hg}^{2+}\right)$; in the atmosphere, mercury is mostly ( $>95 \%$ ) gaseous elemental mercury $\left(\mathrm{Hg}^{0}\right)$. Mercury emitted from point-sources enters into the atmosphere as elemental mercury $\left(\mathrm{Hg}^{0}\right)$, gaseous ionic mercury (reactive gaseous mercury (RGM) which is generally assumed to be mercuric chloride $\left(\mathrm{HgCl}_{2}\right)$ ), and particulate mercury $\left(\mathrm{Hg}^{\mathrm{P}}\right)$ (Lindberg and Stratton 1998; Driscoll et al. 2007; Wiener et al. 2003). The atmospheric lifespan of each
species is between 0.5 to 2 years, 0.5 to 2 days, and 0.5 to 3 days respectively (Driscoll et al. 2007; Wiener et al. 2007).

Oxidation of $\mathrm{Hg}^{0}$ occurs at the solid-liquid interface in cloud and fog droplets, forming the dissolved inorganic divalent mercury species (or mercuric form of mercury: $\mathrm{Hg}^{2+}$ ) which is the most common form found in precipitation (Morel et al. 1998). Atmospheric mercury, once deposited onto the land surface, becomes sequestered in soils largely in the inorganic divalent form $\left(\mathrm{Hg}^{2+}\right)$ bound to organic matter in the humus layer or to mineral constituents in the soil (Lindqvist 1991; Wiener et al. 2003). Soils of the Boreal region are typically organic rich podsols that readily absorb and accumulate mercury. Aquatic ecosystems are protected from the full effects of atmospheric mercury pollution as forest soils sequester atmospheric mercury and watersheds typically act as sinks (Grigal 2002; Bishop et al. 2009b). Based on estimates, terrestrial soils contain the largest inventories of mercury from natural and anthropogenic emissions (Lindqvist 1991; Mason et al. 1994). The global inventory of mercury in surface soils far exceeds the mercury stored in the aquatic or atmospheric compartment (Wiener et al. 2003). The store of mercury as $\mathrm{Hg}^{2+}$ in soils can be reduced and re-emitted into the atmosphere as elemental mercury $\left(\mathrm{Hg}^{0}\right)$ by volatilization or be transported to the aquatic environment where it transforms into other forms of mercury, most importantly the organic form methylmercury ( MeHg having the formula $\mathrm{CH}_{3} \mathrm{Hg}^{+}$) (USGS 1995; Wiener et al. 2003).

The conversion of inorganic forms of mercury to the organic form methylmercury by methylating organisms is a critical component of the mercury cycle (Pollution Probe 2003). Mercury methylation is mediated by microbial activity and is the conversion of both neutral mercury complexes and ionic mercury to methylmercury $\left(\mathrm{CH}_{3} \mathrm{Hg}^{+}\right)$by a methyl-donor group (Ullrich et al. 2001; Wiener et al. 2003). A variety of microorganisms are known to be involved in the mercury methylation process including sulfate-reducing bacteria (SRB) which are believed to be the most important methylating agents in anaerobic sediments (Ullrich et al. 2001). The SRB mediate the methylation of inorganic mercury and produce sulfide as a metabolic byproduct of microbial respiration (St. Louis et al. 1994; Branfireun et al. 1996; Benoit et al. 1999). The transformation of inorganic mercury to methylmercury primarily occurs in semianoxic environments of lake sediments and wetlands (Wiener et al. 2003). Within the bottom sediments of lakes, sulfate reduction is greatest in the uppermost 5 cm at the oxic-anoxic interface of aquatic environments (Wiener et al. 2003). In wetland porewater, lower sulfate
levels and the corresponding increase in methylmercury were attributed to sulfate reduction by bacterial activity (Selvendiran et al. 2008). Mercury methylation also occurs to a lesser extent in aerobic freshwaters, on floating periphyton mats, on the roots of some floating aquatic plants, in the intestines of fish, and on the mucosal slime layer of fish (Wiener et al. 2003). Ironreducing and methanogenic bacteria also have potential to methylate mercury (Ullrich et al. 2001; Fleming et al. 2006). At the same time, sulfate reducers and methanogenic bacteria both possess the ability to demethylate mercury in freshwater sediments (Ullrich et al. 2001). Demethylation processes that degrade methylmercury by microbial action or photodegradation are operating simultaneously in terrestrial and aquatic ecosystems but in aquatic systems the rate of methylation typically exceeds that of demethylation (Ullrich et al. 2001; Wiener et al. 2003). Thus, methylation and demethylation are complicated processes affecting the methylmercury concentrations in aquatic food webs (Wiener et al. 2003).

Aquatic organisms take up both mercury and methylmercury but methylmercury is assimilated more efficiently than ionic mercury (Mason et al. 1994). Mercury assimilation efficiency varies by species and is 5-10 fold higher for methylmercury than inorganic mercury (Stokes and Wren 1987; Trudel and Rasmussen 1997). A process known as "bioaccumulation" occurs when organisms take up contaminants, such as the inorganic and organic forms of mercury, more rapidly than their bodies can eliminate them (Pollution Probe 2003). Mercury bioaccumulation can also result from the direct uptake of mercury across fish gills (Ponce and Bloom 1991).

In freshwater food webs, trophic scale interactions with mercury begin with the bioaccumulation of ionic mercury and methylmercury by primary producers (Driscoll et al. 2007). The inorganic forms of mercury are excreted rapidly compared to methylmercury which is more efficiently absorbed and accumulated (Trudel and Rasmussen 1997). Fish are able to assimilate 65 to $80 \%$ of the methylmercury present in the food they eat (Wiener et al. 2003). An increase in the ratio of methylmercury to inorganic mercury contributing to the total mercury concentration occurs with each additional step in the trophic level (Tan et al. 2009). Thus, the predominance of methylmercury in fish is a consequence of the greater trophic transfer efficiency of methylmercury from food and slower rates of methylmercury excretion relative to inorganic mercury (Trudel and Rasmussen 1997). The trophic transfer of methylmercury is more efficient with each step in the food chain and average contribution that MeHg makes to the total

Hg level increases from $10 \%$ in the water column to $15 \%$ in phytoplankton, $30 \%$ in zooplankton, and $95 \%$ in fish (Watras and Bloom 1992; Driscoll et al. 2007). In piscivorous fish it is inferred that $99 \%$ or more of total mercury is methylmercury (Grieb et al. 1990; Bloom 1992).

The trophic transfer of bioaccumulated methylmercury is more efficient with each step in the food chain leading to the process known as "biomagnification" which is the increase in concentration of a contaminant with each additional trophic level (Pollution Probe 2003). Due to bioaccumulation and biomagnification, concentrations of methylmercury in sport fish commonly exceed those in ambient surface water by a factor of $10^{6}$ or $10^{7}$ (Wiener et al. 2003). High mercury levels are most often found in piscivorous fish such as pike, walleye, bass and trout (Wiener et al. 2003).

## Contamination of Aquatic Ecosystems

The long range transport and deposition of anthropogenically-derived mercury is largely responsible for the elevated mercury concentrations in fish of remote areas (Fitzgerald et al. 1998). Atmospheric modelling of mercury deposition has shown that the Great Lakes region can be influenced from sources up to 2000 km away (Cohen et al. 2004). Lake sediment cores from mid-continental United States of America show that the atmospheric deposition of mercury has tripled in the past 140 years (Swain et al. 1992). Mercury concentration in lake sediment cores from central and northern Canada and Hudson Bay have increased on average by 2 fold over the past half century (Lockhart et al. 1998). At the Experimental Lakes Area in northern Ontario, the anthropogenic component of current mercury inputs was calculated to be approximately $9 \mu \mathrm{~g} \mathrm{~m}^{-2}$ $\mathrm{y}^{-1}$ (Lockhart et al. 1998). An estimated $96 \%$ of the mercury that is being deposited to Canada's land and water every year comes from foreign emission sources (Fitzgerald et al. 1998; Canada Gazette 2011).

In recognition of the global nature of mercury pollution, international action was taken through the United Nations Environment Programme (UNEP) to establish a committee with a mandate to prepare a legally binding document with global standards for mercury emissions for 2013 (Canada Gazette 2011). If no action is taken to reduce global mercury emissions, the estimated cost of global mercury pollution is projected to be $\$ 10$ billion a year by 2020 (Pacyna et al. 2008).

## Health Impacts and Human Fish Consumption Guidelines

Despite Canada's decreased emissions, thousands of recreational fish consumption advisories are issued each year in Canada due to the persistent nature of mercury and increased industrialization in other countries (Canada Gazette 2011). For the general population, the main route of exposure to methylmercury is consumption of contaminated fish and other seafood (Health Canada 2007). Coastal Arctic communities are also exposed to mercury through consumption of marine mammals (Van Oostdam et al. 2005; Donaldson et al. 2010). Canada's aboriginal people are faced with health concerns when relying on a traditional diet high in fish and marine mammals. At the same time, fish are an excellent source of high quality protein with many nutritional benefits and are an essential component of a traditional diet for many Canadians (Health Canada 2007). It is difficult to show a definite correlation between consumption of contaminated fish and direct clinical effects caused by methylmercury exposure (Wheatley and Paradis 1995). Therefore, considering the risk of methylmercury exposure along with the many health benefits of fish consumption, consumers are advised to modify their behaviour by choosing lower risk species and sizes of fish for consumption rather than decreasing their overall fish consumption (Health Canada 2007; Dórea 2008).

Once humans ingest methylmercury from contaminated food, roughly $95 \%$ is absorbed in the gastrointestinal tract and distributed to all tissues in the body as it is bound to the hemoglobin in red blood cells (Díez 2008). Methylmercury is slowly metabolized; the half-life of methylmercury in the body is about 50 days, with a range of 20 to 70 days (Díez 2008). The toxic effect of mercury negatively impairs the reproductive, nervous, cardiac, immune and endocrine organ systems (Wolfe et al. 1998; Sams 2004; Clarkson and Magos 2006; Mergler et al. 2007; Scheuhammer et al. 2007; Tan et al. 2009; Sandheinrich and Wiener 2011).

The developing human fetus is extremely sensitive to methylmercury exposure as it easily crosses the blood-brain barrier and placental membrane and can lead to neurological damage and impaired development (Health Canada 2007; Díez 2008). Methylmercury has been shown to impact cognitive development, measured as intelligence quotient (IQ), in children whose diet contained a large portion of seafood (Pacyna et al. 2008). In addition to the neurological development abnormalities, infants exposed to methylmercury in utero have exhibited delays in walking and talking, cerebral palsy, altered musclar tone, and deep tendon reflexes (Díez 2008). In adults, mercury exposure can increase the risk of cardiovascular
diseases, especially myocardial infarction (Pacyna et al. 2008). Physical lesions in the brain can damage the central nervous system resulting in tingling and numbness in fingers and toes, malaise, impaired balance, loss of coordination, difficulty walking, generalized weakness, impairment of hearing or vision, impaired speech, tremors, and loss of consciousness leading to death (Health Canada 2007; Díez 2008).

Canada's federal, provincial and territorial governments play a role in protecting the public's health from the hazards of mercury by issuing mercury standards for fish inspections and offering consumption advice. In 2007, Health Canada changed its risk management strategy to reduce the threat of unacceptable mercury exposure from the retail sale of fish by strengthening the standards based on a new synthesis of knowledge on the health hazards of methylmercury. The Health Canada standard for total mercury allowable in commercially sold fish, which is enforceable by the Canadian Food Inspection Agency, is 0.5 ppm (Health Canada 2007). The 0.5 ppm standard applies for all species of fish except for certain long-living piscivorous fish that are consumed less frequently: shark, swordfish, escolar, marlin, orange roughy, and fresh/frozen tuna, which are subject to a 1.0 ppm total mercury standard (Health Canada 2007). At the moment, Canada's higher-risk standard is equivalent to the American "action level" of 1.0 ppm for total mercury in all commercial fish. However, this standard set by the United States Food and Drug Administration (FDA) is currently under reassessment (FDA 2011).

Health Canada offers consumption advice based on the tolerable daily intake (TDI) standard. For women of childbearing age, pregnant women, and young children the TDI for methylmercury is 0.2 micrograms per kilogram body weight per day ( $0.2 \mu \mathrm{~g} / \mathrm{kg} \mathrm{bw} / \mathrm{day}$ ). For the general population, Health Canada employs the methylmercury TDI that was developed by the joint FAO/WHO committee on Food Additives, which is 0.47 micrograms per kilogram body weight per day ( $0.47 \mu \mathrm{~g} / \mathrm{kg}$ bw/day) (Health Canada 2007).

The provincial and territorial governments are responsible for implementing contaminant monitoring programs and issuing consumption advisories for sport fish in Canada. For the Province of Ontario, the Ministry of Natural Resources and the Ministry of the Environment work together to produce the biennial "Guide to Eating Ontario Sport Fish". The Ministry of the Environment determines what fish, based on size and species, are suitable for human consumption. The consumption restriction calculations for sport fish include consideration for all
contaminants and are such that "No one shall exceed their tolerable daily intake (over a one month period) for any contaminant in sport fish if they follow the advice in the Guide" (Environment Canada 2001). Consumption restrictions for women of child-bearing age and children under 15 begin at 0.26 parts per million ( ppm ) and total restriction is advised for levels over 0.52 ppm of total mercury in fish. For the general public, fish consumption restrictions start at 0.61 ppm and total restriction is advised for levels over 1.84 ppm total mercury (OMOE 2009). Similarly, The Great Lakes Fish Advisory Workgroup (2007) recommends consumption bans for fish mercury levels $>0.95 \mathrm{ppm}$ (wet weight).

## Northern Ontario Lakes and Fish Communities

The distribution of Ontario's fish fauna is mostly a consequence of geological and ecological forces (Radforth 1944; Hartviksen and Momot 1987; Holm et al. 2009). The topography of northern Ontario and the formation of drainage basins is a relic of the last episode of glaciation which occurred 100,000 to 18,000 years ago (Holm et al. 2009). After the continental ice sheets disappeared approximately 6,000 years ago, the land rebounded upwards forming the watersheds that are present today (Holm et al. 2009). Following glacial retreat, fish movement occurred between connected waterways. The coldwater species of fish (communities dominated by lake trout [Salvelinus namaycush]) were the first to colonize Ontario's new formed lakes followed by the coolwater species (communites dominated by walleye and northern pike [Esox lucius]) (Holm et al. 2009). The newly formed watersheds formed a physical barrier to fish movement. However, human interference on fish movement has allowed species to move past their historical range (Holm et al. 2009).

There are three distinct fish communities present in the lake, river, and wetland habitats of Ontario's Boreal region (Browne 2007). In the lakes and rivers of the Boreal Shield zone, walleye and northern pike are the most common top predators and are the most widely distributed community type (Browne 2007). Although walleye and pike often feed on similar prey, their diets diverge considerably due to their feeding habits. Northern pike are sit-and-wait predators that inhabit shallow inshore areas of lakes and slow moving waters of rivers with abundant structure such as aquatic vegetation or fallen trees (Browne 2007). Walleye are roaming predators that inhabit both slow and fast current areas of rivers as well as both nearshore and offshore lake environments (Browne 2007). The diet of northern pike is dominated by
minnows, white suckers, and yellow perch, whereas the diet of walleye is dominated by yellow perch, cisco, and minnows. Walleye and northern pike also prey on one another (Scott and Crossman 1973).

Lake trout/whitefish/cisco communities are a less common community type with the majority of occurrences in the western half of northern Ontario (Browne 2007). Lake trout, lake whitefish, and cisco inhabit deep ( $>8 \mathrm{~m}$ ), low productivity lakes. In autumn, lake trout move into the shallows in preparation for spawning. After spawning, lake trout disperse freely within the entire lake at various depths and remain dispersed throughout the winter months. In spring, lake trout occur in shallow surface waters immediately after the break-up of ice. Lake trout retreat to the cooler deep water of the hypolimnion during the warm summer months. Lake trout are predaceous and feed on a broad range of organisms (zooplankton, freshwater sponges, crustaceans, aquatic and terrestrial insects, many species of littoral and pelagic fishes, other lake trout, and small mammals) (Scott and Crossman 1973; Browne 2007). Food varies with season, particularly in small lakes where a thermal barrier constricts their foraging environment (Scott and Crossman 1973).

The third community type, the brook trout (Salvelinus fontinalis) community, is commonly associated with the major rivers, tributary streams, and creeks as well as lakes and beaver ponds (Browne 2007). Brook trout are most abundant in waters with depauperate fish communities. Lake-dwelling populations are rare in the north due to the presence of other top predators such as walleye, perch, and northern pike which are competitors and predators of brook trout (Browne 2007).

## Mercury in Fish of Northern Ontario

Methylmercury contamination of fish is a global problem that has diminished the recreational, economic, and nutritional benefits derived from fisheries resources in many fresh waters (Sandheinrich and Wiener 2011). Mercury accounts for $80 \%$ of the fish-consumption advisories in the United States and $97 \%$ of the fish consumption advisories in Canada (U.S. EPA 2009; U.S. EPA 2001). In Ontario, mercury is the main contaminant which accounts for $86.3 \%$ of all fish contaminant consumption restrictions from inland water bodies (OMOE 2009; OMOE 2011). Consumption restrictions due to mercury alone are particularly common in remote inland
locations (OMOE 2011). Many of Ontario's inland lakes and rivers contain fish with high mercury concentrations which may vary widely between and within systems.

In Canada and Scandinavia, forestry harvesting activities have been shown to increase mercury concentrations aquatic ecosystems and biota (Garcia and Carignan 1999, 2000, 2005; Lamontagne et al. 2000; Porvari et al. 2003; Desrosiers et al. 2006). The physical and chemical characteristics of the waterbody as well as the degree of impact from human activities will influence the formation and bioavailability of methylmercury (Kidd et al. 2012). Mercury levels in fish may become elevated if methylmercury at the base of the food web is enhanced by significant influxes from external sources, high in situ rates of production in bed sediments and anoxic hypolimnia, or a combination of biogeochemical, biological, trophic and human factors (Kidd et al. 2012).

Watershed characteristics and human influences on the processes that affect mercury bioaccumulation and biomagnification are particularly important when evaluating mercury contamination in fish (Kidd et al. 2012). Past studies have shown a range of responses from watershed influences, such as wetlands, wildfire, and forest harvesting, on influencing mercury dynamics and concentrations in the water and biota in freshwater lake ecosystems. As landscape characteristic data are widely available through satellite mapping and GIS spatial layers, this wealth of knowledge provides an opportunity to determine the associations of watershed characteristics with mercury concentrations in fish across a large spatial scale.

## Thesis Objectives

The purpose of this research was to evaluate the relationship between fish mercury concentrations and various lake and watershed scale characteristics. There are unanswered questions regarding why certain fish populations have higher mercury concentrations than those of neighbouring lakes. The variability in fish mercury concentrations should be explained by spatial attributes of the watershed, lake characteristics, and characteristics of the fish population.

Chapter 1 of this study will: 1) investigate the association of methylmercury in fish tissues with the amount of disturbance (natural or human caused) that has occurred within the watershed of a lake, as well as 2 ) investigate the association of methylmercury in fish tissue with
lake and watershed scale variables that are believed to influence mercury bioavailabilty in the aquatic environment.

Chapter 2 examines the associations between walleye mercury concentrations and specific population characteristics.

## Study Area

Lakes and watersheds in this study are located in Fisheries Management Zones (FMZs) 4, 6, 7, 8, 10, and 11 (Figure 0.1). The study area spans the Boreal Forest and Great Lakes-St. Lawrence Forest Regions of the Boreal Shield Terrestrial Ecozone which is where the majority of forest harvesting occurs within the Province's Area of the Undertaking (OMNR 2010b). The total area of the province managed for forest harvesting is 26.2 million hectares (OMNR 2010b). Between the years 2008 to 2009, approximately 123,387 hectares (ha) of Crown Forest Land were harvested where the clearcut silvicultural system was used for the vast majority of this area (OMNR 2010b).

Wiken (1986) described the Boreal Shield Ecozone as having abundant precipitation and well irrigated land with a multitude of lakes containing approximately $10 \%$ of Canada's freshwater. The topography, having been shaped by glaciation and postglacial deposition, is a massive rolling plain of ancient bedrock. The climate is continental with long cold winters and short warm summers. Numerous bogs, marshes and other wetlands cover this ecozone (Wiken 1986).

## 1. Mercury Associations with Catchment and Lake Scale Variables

## Introduction

A significant fraction of the methylmercury in biota from remote or semi-remote regions is derived from anthropogenic mercury entering the aquatic ecosystem or its watershed from atmospheric deposition (Wiener et al. 2003). However, quantifying the relative contribution of natural and anthropogenic emissions to the methylmercury in aquatic life at remote and semiremote locations is an enormous scientific challenge due to the spatial variation in natural sources of mercury and the biogeochemical transformations and transport of mercury within the landscape (Wiener et al. 2003). Fish methylmercury concentrations are largely influenced by a combination of watershed and lacustrine factors that exert controls on the production and bioaccumulation of methylmercury (Wiener et al. 2006).

Lake basin characteristics have shown associations with mercury concentrations in biota of Boreal lakes (Bodaly et al. 1993; Garcia and Carignan 1999; Garcia and Carignan 2000; Garcia and Carignan 2005; Garcia et al. 2007). Past studies have evaluated morphometric parameters (mean depth, maximum depth, lake surface area, lake volume, watershed area, ratios of watershed area to lake size or ratios of epilimnetic area to lake size) that relate to temperature and water chemistry as potential variables contributing to mercury variability in biota (Ramlal et al. 1993; Bodaly et al. 1993; Garcia and Carignan 1999). Lake size is an important variable influencing the mercury concentrations in fish (Bodaly et al. 1993). Bodaly et al. (1993) found an inverse relationship between lake size and mercury concentrations of planktivorous, omnivorous, and piscivorous fish in a study of six remote lakes in northwestern Ontario. Lake temperature, which is related to basin area, lake area and lake volume, influences rates of mercury methylation. Higher water temperatures and increased methylation in warm littoral sediments may explain the negative correlation between lake size (or volume) and fish mercury concentrations (Bodaly et al. 1993; Evans et al. 2005). Small lakes have a greater temperature variation than large lakes as they are generally shallower and typically respond faster to changes in atmospheric temperature, making them warmer in the summer and colder in the winter; a greater range in temperature could lead to higher rates of methylation compared to demethylation (Bodaly et al. 1993). Another explanation for the results found by Bodaly et al. (1993) may be that there is more efficient solute and sediment transport to lakes with smaller watersheds
(Gabriel et al. 2009). Likewise, the proportionate flux of allochthonous inputs of organic matter and complexed mercury from the watershed may have a greater influence on smaller lakes (Greenfield et al. 2001).

Studies of lake systems have found correlations between water chemistry and fish mercury concentrations. Water chemistry can influence the production, availability and bioaccumulation of methylmercury. Mercury speciation, a principal factor governing the methylation potential of a system, is strongly influenced by chemical conditions, notably redox, pH , organic ligands, and inorganic ligands (Wiener et al. 2003). Dissolved organic carbon (DOC) and pH are the two most documented water chemistry parameters associated with mercury biochemistry (Gabriel et al. 2009). Nutrients, primarily total phosphorus or total nitrogen, will control ecosystem productivity and may influence mercury accumulation in aquatic biota (Garcia and Carignan 1999; Rypel 2010).

The mercury and sulfur cycle are intimately linked in the aquatic ecosystem as both are mediated by bacterial controls. Sulfate reducing bacteria (SRB) and methanogenic bacteria methylate and demethylate mercury in freshwater ecosystems but the rate of methylation typically exceeds that of demethylation (Ullrich et al. 2001; Wiener et al. 2003). The speciation of sulfur is a major controller on the net methylation rate of mercury in many ecosystems (Munthe et al. 2007). The presence of sulfate stimulates the methylation of mercury by sulfatereducing bacteria, while excess sulfide may reduce the bioavailability of mercury by forming mercury sulfide complexes which are immobilized in the sediments (Gilmour et al. 1992; O’Driscoll et al. 2005; Muthe et al. 2007). Under oxidized conditions in soil and water more than $99.9 \%$ of mercury and methylmercury in the aqueous phase is bound to organic sulfur groups (thiols or "-RSH" groups) forming metal-thiol complexes (Skyllberg p 40. In Bishop et al. 2009b). When oxygen is depleted because of microbial degradation of soil organic matter under water saturated conditions the redox-potential decreases to reduced conditions and the mercuric ion $\left(\mathrm{Hg}^{2+}\right)$ shifts its affinity from organic complexes to inorganic sulfide complexes (Morel et al. 1998; Gabriel and Williamson 2004; Skyllberg p 40. In Bishop et al. 2009b). Enhanced mobilization of mercury and formation of dissolved Hg-sulfides occurs when disturbance events alter the hydrologic cycle. Increased lateral transport of mercury and increased concentrations of dissolved inorganic sulfides and energy-rich organic matter will result in ideal conditions for the enhanced production of methylmercury by SRB.

The relationship between dissolved organic matter (DOM), commonly measured as dissolved organic carbon (DOC), and mercury is very complex with studies showing differences in the association between DOM and mercury accumulation in fish (Gabriel et al. 2009). Dissolved organic matter can bind trace metals and affect the speciation, solubility, mobility and toxicity of mercury in the aquatic environment (Ravichandran 2004). Dissolved organic matter may enhance or retard methylation of mercury, serve as a transport mechanism for mercury from terrestrial areas, or reduce the bioavaliability of inorganic and organic mercury species by binding to reaction sites (Ravichandran 2004). The enhanced mobility and transport of $\mathrm{Hg}-\mathrm{DOM}$ complexes results in increased water column concentrations of mercury in otherwise pristine lakes and rivers (Ravichandran 2004). Dissolved organic matter also has the potential to enhance methylation of mercury by stimulating microbial growth (Ravichandran 2004). Dissolved organic carbon may have a positive influence on fish mercury concentrations (McMurty et al. 1989; Wren et al. 1991; Rencz et al. 2003; Belger and Forsberg, 2006; Driscoll et al. 2007). However, a negative correlation between THg in several species of fish and lake water DOC (or water colour used as an indicator of DOC) has frequently been documented (Grieb et al. 1990; Snodgrass et al. 2000; Greenfield et al. 2001; Gabriel et al. 2009). Complexation of mercury with DOC may limit the amount of inorganic mercury available to methylating bacteria since DOC molecules are typically too large to cross the cell membranes of the bacteria (Ravichandran 2004). Thus, dissolved organic carbon may prevent the biological uptake and methylation of ionic mercury within a waterbody (Munthe et al. 2007). Moreover, DOC is suspected to enhance photoreduction of $\mathrm{Hg}^{2+}$ to $\mathrm{Hg}^{0}$ further reducing the bioavailability within an aquatic environment (O'Driscoll et al. 2003; Hall et al. 2008; Gabriel et al. 2009). Thus, contradictory results may be due to multiple ecological factors that complicate the net effect of lake water DOC concentrations on mercury concentrations in fish.

Fish mercury concentrations are often highly negatively correlated with pH (Cope et al. 1990; Sun and Hitchin 1990; Wiener et al. 1990). Acidic lakes with low buffering capacity typically have higher fish mercury concentrations due to multiple factors related to fish metabolism and molecular Hg bioavailability (Gabriel et al. 2009). Biochemical pathways for microbial production of MeHg are favoured at a low pH in the water column and at the sediment water interface. Methylation occurs more readily at the sediment-water interface since the pH and oxygen are lowest and mercury is more bioavailable with fewer chemical associations
between inorganic mercury species and DOC (Ravichandran 2004). Additionally, under more acidic conditions, the production of monomethylmercury is favoured over dimethylmercury (Winfrey and Rudd 1990). Dimethylmercury has a higher volatility and is less stable in the water column; thus, at lower pH there is a decreased loss of volatile mercury from lake water (Winfrey and Rudd 1990). Acidic conditions favour methylation and sulfide production by SRB (Snodgrass et al. 2000). Moreover, bioaccumulation processes can influence the relationship between pH and fish mercury concentrations. Even if MeHg concentrations in the lakes are not high, a low pH can increase gill permeability and decrease the growth rates of aquatic biota resulting in elevated MeHg in fish (Winfrey and Rudd 1990). Greenfield et al. (2001) found pH to be the most important factor in determining THg in yellow perch. Similarly, Garcia and Carignan (2000) found pH to be the most important predictor of Hg concentrations in northern pike.

Differences in mercury transformations, cycling, and bioavailability can result from interlake differences in landscape features (Bodaly et al. 1993; Watras et al. 1995; Wiener et al. 2006). Munthe et al. (2007) suggested that watershed size and watershed to lake surface area ratios are the most important determinants for mercury delivery to aquatic systems. The magnitude of water chemistry response to disturbance in Boreal Shield lakes has been shown to be directly proportional to the ratio of disturbed area within the watershed to the lake's volume or area (Carignan et al. 2000; Garcia and Carignan 2005). Similarly, the concentration of mercury in aquatic biota has been correlated to forest-harvesting disturbance within the watershed of Boreal Shield lakes (Garcia and Carignan 1999; Garcia and Carignan 2005). However, larger watersheds may have lower mercury inputs from the watershed due to less efficient transport and increased loss processes (Munthe et al. 2007). Thus, watershed processes partly explain why mercury concentrations can vary five-fold among fish from neighbouring lakes receiving the same precipitation (Sorensen et al. 1990; Wiener et al. 2006; Munthe et al. 2007).

Wetlands play a significant role in the hydrologic cycle (Bullock and Acreman 2003) and are important sources of mercury to boreal aquatic ecosystems (Watras et al. 1995; St. Louis et al. 1996). The influence of contiguous wetlands on the mercury budget of a lake depends on the wetland location within the watershed and its hydrologic connectivity with the groundwater system and downstream channel network (Bullock and Acreman 2003). Ecosystems with
abundant wetlands have shown elevated mercury concentrations in the aquatic biota (Wiener et al. 2006; Castro et al. 2007; Simonin et al. 2008; Rypel 2010). Although percent wetland area has been used in modeling mercury in biota, the relationships between wetlands and mercury in fish is still largely undefined.

Remote wetlands receive most of their mercury from atmospheric deposition. Newly deposited mercury complexes with the organic matter produced in wetlands within the top soil layer, enhancing the accumulation in soils (Driscoll et al. 2007). Atmospherically derived mercury is readily methylated in the organic-rich, anoxic sediments of boreal wetlands (St. Louis et al. 1996). From the wetland, mercury is easily mobilized and transported to hydrologically connected lakes by connected streams or shallow groundwater flow (Wiener et al. 2006). High rainfall, surface runoff, and human disturbance of wetlands promote the release and transport of mercury complexed with organic matter to lakes (Watras et al. 2005). A peatland study conducted at the Experimental Lakes Area Reservoir Project (ELARP) showed a four fold to fifteen fold difference in MeHg yield in rivers from watersheds containing peatlands compared to upland forested watersheds (St. Louis et al. 1994). Although yields of MeHg vary from one wetland to another, wetland areas in the watershed are sites of net methylmercury production (St. Louis et al. 1994). Yields of methylmercury from the wetland portion of the watershed were 2679 times higher per unit area than from upland areas (St. Louis et al. 1994).

Wetlands differ in their vegetation and biogeochemical processes because of differences in hydrology; thus, there are large consistent differences among wetland types in relation to MeHg production and export (St. Louis et al. 1996). However, all wetland types have been shown to produce more MeHg during years of high water yield (St. Louis et al. 1996). St. Louis et al. (1996) concluded it is possible to model inputs of MeHg into lakes based on the percentage wetland area, the type of wetland, and the annual water yield of each watershed.

The influence of wetlands within the watershed has been shown to vary according to lake size. In a northern Wisconsin study, fish mercury levels in 43 lakes of different morphometry (drainage lakes, headwater lakes, and seepage lakes) were analyzed in relation to water chemistry, trophic ecology and spatial traits (watershed area, surrounding wetland abundance, and lake hydrologic position) (Greenfield et al. 2001). Wetland abundance only correlated with elevated fish mercury levels for small ( $<64 \mathrm{ha}$ ) drainage lakes with greater than $6 \%$ wetland in their watershed (Greenfield et al. 2001).

In remote environments, watershed characteristics such as wetlands may result in local areas, referred to as "methylmercury hot spots", which have increased mercury levels compared to the surrounding landscape as a consequence of increased mobility and methylation of atmospherically deposited mercury (Mills et al. 2009). These low-lying wetland hot spots may receive increased fluxes of mercury, associated with DOM or inorganic sulfides from the terrestrial area following increase lateral flow from clear-cutting disturbance (Bishop et al. 2009b). Spatial variability also exists within wetlands in terms of net MeHg production (Mitchell et al. 2008). Methylmercury concentrations were greatest around the fringes of peatlands where net production and accumulation of MeHg was higher. Hydrological mixing of solutes such as sulfate and labile carbon that accumulate in this fringe area around wetlands thereby enhances the net production of MeHg (Mitchell et al. 2008).

Boreal Canadian Shield watersheds serve as large reservoirs of mercury that shed their metal load when the soil, vegetation, and land hydrology are disrupted (Desrosiers et al. 2006). The podsolic soils of the boreal Canadian Shield forest readily adsorb and accumulate mercury from wet and dry atmospheric deposition (Desrosiers et al. 2006). Soils may also serve as a long-term source of mercury to surface waters (Hultberg et al. 1995; Gabriel and Williamson 2004). Soil cover may be an important watershed factor related to mercury variability in fish among lakes as consistent correlations between fish THg levels and upland THg levels in the soil A -horizons and O-horizons were found in lakes of the southern Boreal Shield (Gabriel et al. 2009). Moreover, forest canopy type and density have an important influence on mercury deposition (Witt et al. 2009). In the Boreal forest, the highest total mercury and methylmercury concentrations in throughfall were measured beneath dense conifer canopies with high leaf surface area (Witt et al. 2009). Studies at the Experimental Lakes Area show that forest canopies effectively collect mercury from the atmosphere resulting in up to 8 times more mercury deposited in a forested watershed compared to other types of open ecosystems (Environment Canada Presentation: St. Louis and Graydon 2011). Consequently, the effective scavenging abilities of the boreal forest to capture atmospheric mercury may increase the risk of mercury related water quality issues in conifer-dominated systems (Witt et al. 2009).

Land-use changes and anthropogenic disturbances may significantly increase mercury export from the watershed (Munthe et al. 2007). Disturbance within the watershed can alter the transport, transformation, and bioavailability of mercury in surface water (Driscoll et al. 2007).

Mercury has been shown to increase in bioavailability when water levels are raised for hydroelectric development (Hecky et al. 1991; Bodaly et al. 1997), forests are clear-cut (Garcia and Carignan 2005; Garcia et al. 2007), water levels are lowered for dewatering of muskeg for gem or mineral deposits (Lean 2007), and when water chemistry is affected (Lindqvist et al. 1991).

Water level manipulations within existing reservoirs and reservoir creation can elevate mercury levels in biota (Evers et al. 2007). The flooding of soils during reservoir creation yields a flux of mercury and detrital matter to the associated water in addition to forming an ideal methylating environment along the newly formed soil-water interface (Evers et al. 2007). Similar environments are created by water level fluctuations caused by damming, since the littoral zones are ideal environments for methylation because bacterial sulfate reduction is promoted under transitioning reduction-oxidation conditions (Evers et al. 2007). Schetagne and Verdon (1999) observed fish mercury increases of 1.5 to 4 times the natural background levels with concentrations peaking 10 to 15 years after dam construction. Once reservoirs are no longer manipulated or managed it is expected to take 20 to 40 years for fish mercury concentrations to return to initial background levels (Schetagne and Verdon 1999).

In much of the boreal climatic zone silviculture is the most widespread and important anthropogenic influence on watershed processes (Kreutzweiser et al. 2008). Researchers have only recently begun to investigate the effects of forest harvesting on the mercury dynamics in aquatic environments (Browne 2007). During the last century, forest harvesting disturbance has exceeded forest fire as the primary disturbance agent in vast areas of the Boreal forest (Carignan et al. 2000). Logging disturbance can alter the biogeochemical processes of boreal forest watersheds by changing the forest composition, plant uptake rates, soil conditions, moisture and temperature regimes, soil microbial activity and water fluxes (Carignan and Steedman 2000; Kreutzweiser et al. 2008). Forest harvesting alters the hydrologic cycle, soil processes, and plant communities thereby increasing the risk of altering the cycling and bioavailability of mercury in the terrestrial and aquatic ecosystem (Porvari et al. 2003; Garcia and Carignan 2005). Forest harvesting disturbance may severely change the soil structure by compaction from logging equipment and lead to hydrological flushing of nutrients and dissolved organic carbon from surficial organic soil layers into surface waters as a result of an elevated water table (Carignan and Steedman 2000).

Enhanced methylation of mercury and increased mobilization of mercury occurs once clearcutting alters the forest hydrology and soil conditions. Reduced evapo-transpiration following fires and forest harvesting causes a rise in the groundwater table creating an anoxic environment in the flooded terrestrial soils (Garcia et al. 2007; Munthe et al. 2007). Decomposing organic material resulting from forest harvesting slash and increased sun exposure creates favourable warm and moist soil conditions where enhanced methylation occurs by sulfate reducing bacteria (Munthe et al. 2007). Increased DOC exports from logged watersheds can act as a vector for dissolved Hg from the terrestrial watershed to the lakes, thereby increasing the THg and MeHg concentrations in the aquatic ecosystem (Garcia et al. 2007). Increased levels of MeHg in runoff have persisted for greater than five years following logging and soil disturbance (Munthe et al. 2007). In southern Finland, significant increases of THg and MeHg were observed in the runoff from a small spruce forest after clear-cutting and soil treatment (Porvari et al. 2003). Five years following clear-cutting the median MeHg concentration in runoff was 1.9 times greater than before forest harvesting (Porvari et al. 2003). Comparable to forest harvesting, forest clearing after severe storm-fell events can lead to large increases in MeHg from forest soils to surrounding waters much to the same extent as clear-cutting (Munthe et al. 2007). Similarly, a temporary logging track inadvertently placed across a small brook in the Swedish long-term Gårdsjön reference watershed increased the annual outputs of MeHg by more than 3 fold for longer than half a decade (Munthe and Hultberg 2004).

Forest fire disturbance also impacts the cycling of mercury within the watershed ecosystem. The influence of fire on mercury dynamics depends on the watershed characteristics, the extent of damage to the soil organic layer, and associated changes in water chemistry (Carignan et al. 2000; Allen et al. 2005). Forest fires can promote mobilization of soil-bound Hg by increased leaching of DOC from the watershed. However, most of the mercury stored in fuel (forest litter) within the watershed is volatilized in the smoke from high intensity forest fires (Friedli et al. 2001; Sigler et al. 2003). Almost all ( $>95 \%$ ) of the Hg volatilized by fire is elemental mercury (Friedli et al. 2001). The re-emitted mercury from fire is a significant component of the atmospheric mercury cycle as it represents an estimated 1.6 to $8 \%$ of all total mercury emissions worldwide (Friedli et al. 2001). Furthermore, forest fire has been shown to increase mercury accumulation by fish following nutrient export which caused increased productivity and restructuring of the food web (Kelly et al. 2006). The elevated Hg concentrations in fish
following fire were a result of increased trophic position due to dietary alterations from Hyalella (detrivore) to increased piscivory and consumption of Mysis (zooplanktivore) (Kelly et al. 2006).

Major watershed perturbations can alter mercury export rates from the watershed and influence in-lake reactions that determine the fate of mercury within aquatic biota (Garcia and Carignan 2005). Fire and forest harvesting both affect runoff and DOC loading to lakes and have the potential to increase Hg-bound organic matter to lakes (Lamontagne et al. 2000; Kreutzweiser et al. 2008). Dissolved organic carbon concentrations were three-fold higher and lake water phosphorus and nitrogen concentrations increased by approximately two-fold in lakes with clear-cut watersheds (Carignan et al. 2000). Increased export of dissolved nutrients and DOC from the watershed caused subsequent short-term changes in the water quality resulting in implications for the ecological processes and biotic communities of receiving waters (Kreutzweiser et al. 2008). Following the increase in DOC after logging, mercury bioavailability was significantly higher at the base of the food chain and a concurrent increase in mercury levels was observed in the aquatic organisms (Garcia and Carignan 2005).

Piscivorous fish in lakes with harvested watersheds showed higher total mercury levels relative to fish in burned or reference lakes (Garcia and Carignan 2000). Garcia and Carignan (2000) observed significantly higher concentrations of mercury (expressed on a dry weight basis) in $560-\mathrm{mm}$ northern pike of logged headwater lakes $(3.4 \mu \mathrm{~g} / \mathrm{g}, \mathrm{n}=4)$ compared to northern pike of reference lakes ( $1.9 \mu \mathrm{~g} / \mathrm{g}, \mathrm{n}=8$ ). The logged lakes had $11 \%$ to $72 \%$ of the watershed area affected by clear-cut disturbance (Garcia and Carignan 2000). Average mercury concentrations in fish of burned lakes were not significantly different than harvested or reference lakes ( $3.0 \mu \mathrm{~g} / \mathrm{g}, \mathrm{n}=7$ ). Fire affected $50.1 \%$ of the watershed for one lake, and greater than $90 \%$ of the watershed area for six other lakes (Garcia and Carignan 2000). Wetland area was relatively consistent among lakes, and comprised an average of $1.8 \%$ (at the most $6 \%$ ) of the drainage area for the studied lakes (Garcia and Carignan 2000). These Boreal Shield study lakes were relatively small, with a mean lake area of $0.4 \mathrm{~km}^{2}$ ( 40 ha ), and similar with respect to depth and watershed morphometry. All but one were headwater lakes and the variability in fish Hg explained by their statistical model increased from $79 \%$ to $92 \%$ when a second-order lake was removed from the analysis (Garcia and Carignan 2000). Thus explasizing the importance of scale as lake size was an important factor influencing mercury bioavailability within disturbed watershed ecosystems.

Additional research on the same set of lakes demonstrated that trophic position, characterized
by the tissue ratios of stable isotopes $\left(\delta^{15} \mathrm{~N} / \delta^{14} \mathrm{~N}\right)$, was an important factor to consider when comparing fish from different systems with differences in watershed and water characteristics (Garcia and Carignan 2005).The use of trophic position allowed the direct comparison of trends in mercury concentration from fish of lakes subject to different levels and types of watershed disturbance. The mercury concentrations in fish, once normalized to trophic position, were significantly related to the ratio of clear-cut area within the watershed to lake area or lake volume (Garcia and Carignan 2005). The mercury concentration of northern pike, walleye, and burbot was found to be 2 to 3 fold higher for disturbed compared to reference lakes (Garcia and Carignan 2005). Harvesting disturbance affected $9 \%$ to $72 \%$ of the total watershed area for the cut lakes $(\mathrm{n}=9)$, whereas reference lakes $(\mathrm{n}=20)$ had remained undisturbed for 70 years. Total mercury in top predator fish from lakes with partially burned watersheds was less than in cut lakes and did not differ from the undisturbed lakes (Garcia and Carignan 2005).

The effects of changes to lake ecosystems following forest disturbance on fish are not well studied but effects are likely dependent upon the characteristics of the lake and the surrounding landscape (Browne 2007). A synthesis of research available up to 2006 estimated that between $1 / 10$ and $1 / 4$ of the mercury in fish of high-latitude, managed forest landscapes could be attributed to forest management (Bishop et al. 2009). Since this estimate was made, large differences in the magnitude of the mercury response to different forest operation techniques have appeared (Bishop 2011). The watershed and lake ecosystems' response to forest management has ranged from very little observable change to manifold increases of upland leakages and bioaccumulation of methylmercury.

The objective of this chapter was to examine the associations between lake and watershed characteristics and mercury concentrations in common top predator species of fish in northern Ontario lakes. If forest harvesting generally results in an increase in the net export of mercury and production of MeHg within a watershed/lake ecosystem, then I expected lakes with forest harvesting disturbance would have elevated fish mercury concentrations. In addition, variability in fish mercury concentrations was expected to be associated with differences in the spatial attributes of the watershed and lake chemistry characteristics.

The specific objectives of this study were to:

1) Investigate the association between THg in fish tissues with the amount of disturbance (natural or human caused) within the waterbody catchments of the lakes.

I hypothesized that if forest harvesting within the waterbody catchment area increases the net transport of mercury into a lake, thereby increasing mercury methylation and bioavailability, then fish within lakes with forest harvesting within their waterbody catchment would have consistently elevated mercury concentrations relative to fish in lakes with undisturbed waterbody catchments. I predicted that the total amount of mercury in piscivorous fish was negatively related to lake size and positively related to the ratio of (clear cut area within the waterbody catchment / waterbody catchment area).
2) Investigate the association of THg in fish tissue with lake and waterbody catchment scale variables that are believed to influence methylation potential or transport of mercury to the aquatic environment.

At the lake scale, I hypothesized that if lake chemistry affects mercury methylation and accumulation in fish, then elevated fish mercury concentrations would be found in lakes with low pH , high DOC, and high sulfate concentrations.

At the waterbody catchment scale, I hypothesized that if wetlands are effective hotspots of methylmercury production and a major contributor to mercury loading to lakes, then lakes with abundant associated wetlands would have higher fish mercury concentrations compared to lakes with low wetland association, as a result of increased mercury bioavailability. I predicted the concentration of mercury in piscivorous fish would be positively related to the abundance of contiguous wetlands present within the waterbody catchment of a lake. I expected the total amount of mercury in piscivorous fish to be positively related to the ratio of (wetland area within the waterbody catchment / waterbody catchment area).

## Methods

## Study Lakes

In 2008, the Ontario Ministry of Natural Resources (OMNR) implemented the BroadScale Fisheries Monitoring (BSFM) program, a pillar of the new Ecological Framework for Fisheries Management, to monitor the health of Ontario's inland lakes (OMNR 2009). The province of Ontario was divided into 20 management zones among the three main districts (Northwest, Northeast, and Southern Region). The BSFM survey collected basic information on hundreds of lakes across a large geographic area in a short period of time. Survey lakes are representative examples of the Boreal lakes in northern Ontario as they were randomly selected within each management zone (OMNR 2010). For this study a subset of BSFM lakes were selected from Fisheries Management Zones (FMZs) 4, 6, 7, 8, 10, and 11. (Figure 1.1 and Appendix A). One of the main goals of the BSFM is to identify the connections between stresses (natural or human-induced) and condition of aquatic resources (OMNR 2010). Selected study lakes were those for which fish mercury contamination analysis had been conducted by Ontario Ministry of Environment (OMOE). Lakes ranged in size and were grouped according to lake surface area: 33 lakes in bin 1 ( $<100 \mathrm{ha}$ ), 79 lakes in bin 2 ( 100 to 500 ha ), 56 lakes in bin 3 (500-1500 ha), 58 lakes in bin 4 ( 1500 to 5000 ha ), and 17 lakes in bin 5 ( $>5000 \mathrm{ha}$ ). The location coordinates and lake surface areas of study lakes belonging to each FMZ are summarized in Appendix A (Tables A-1 to A-6).

## Geospatial Characterization of Waterbody Catchments

The drainage area defined by the waterbody catchment is the local area that directly contributes rainfall or runoff to a waterbody which consists of all the associated shoreline catchments as well as the waterbody itself but excludes the sub-catchments of upstream lakes (Figure 1.2) (Furnans and Olivera 2000). The waterbody catchment is of particular importance to reservoir planners and water quality modelers (Furnans and Olivera 2000). The waterbody catchment of each lake was delineated from the OMNR's enhanced flow direction grid (version $2.0,20 \mathrm{~m}$ resolution) (efdir) using the Hydrology Tools in the Spatial Analyst extension for ArcGIS (version 9.3.1, developed by the Environmental Systems Research Institute (ESRI)). The efdir is a D8 flow direction grid that was generated by the OMNR's Water Resources

Information Program following methods developed by Kenny and Matthews (2005) to incorporate mapped surface hydrology features (streams, lakes, and other waterbodies) and flow directions interpreted from the Ontario provincial digital elevation model (DEM) (OMNR 2005). The enhanced flow accumulation grid (efacc) was derived from the efdir using ESRI's Hydrology Tools. Waterbody catchment characteristics were quantified using ArcGIS by both analyses of DEM derivatives and geometric intersections with watershed polygons and other spatial data layers (Appendix B). Intersection outputs were written to ArcGIS Personal Geodatabases (PGDb) that were subsequently accessed through Microsoft Access (version 2003). Structured Query Language (SQL) queries were created to summarize waterbody catchment characteristics from geometric intersection output tables.

The spatial attributes of the lake and waterbody catchment (summarized in Table 1.1) were calculated in ArcGIS and summarized in MS Access for each study site (Appendix B: Table B.1). A summary of the provincial datasets that were used to calculate waterbody catchment scale characteristics as well as site specific waterbody catchment characteristics are summarized for each site in Appendix B. Since the effects of watershed disturbance on aquatic biota can often be long lasting, forest harvesting disturbance and natural disturbance (insect damage, blowdown, fire) were summarized from 1990-1999 and 2000-2009 for each waterbody catchment. Elevated mercury concentrations in fish can be observed for 20 to 30 years after severe watershed disturbances as a result of the long turnover time of fish populations due to long lifespans of piscivorous species and the long half-life of MeHg in fish (Bodaly et al. 1997). The climate data (average summer temperature and precipitation according to 1990-1999 and 2000-2009) were obtained in ArcGIS with the Historical Climate Analysis Tool (HCAT 2012).

## Lake Chemistry Collection and Analysis

Spring water quality data were collected by the OMNR and OMOE from select BSFM lakes (Ingram et al. 2006). The whole-lake composite samples were collected from the middle of each lake at a depth of 5 m . Collection of water samples occurred in 2008 and 2009 shortly after ice off while lakes were thermally mixed and a single sample is presumed to represent the entire lake's chemistry (Ingram et al. 2006). Within the perishability limit of 5 days, water samples were shipped and analysed at the OMOE Dorset Environmental Science Centre following standard analytical protocols (OMOE 1983). Water quality parameters that were measured are summarized in Table 1.2 and are presented for each lake in Appendix C (Table C.1).

| Table 1.2. Acronyms and Units of Water Chemistry Variables |  |  |
| :--- | :--- | :--- |
| Acronym | Description | Units |

## Fish Sampling

Fish population information was gathered from the selected lakes during the summer BSFM netting program. Field methodology for the collection of fish involved the North American Large Mesh (NA1) and Ontario Small Mesh (ON2) gill netting procedures (Sandstrom et al. 2011). Fish collected for contaminant sample analysis were netted with the North American large mesh gillnet which has 8 different mesh sizes per gang (stretch measurements: $38,51,64,76,89,102$, $114,127 \mathrm{~mm}$ ) (Sandstrom et al. 2011). Equal allocation of effort was distributed across the depth strata and across all regions of the lake (Sandstrom et al. 2011). Upon fish collection, the length, weight, contaminant sample, and ageing structures were taken. From each lake, typically 10 to 20 fish tissue samples (consisting of approximately 50 g of lean, dorsal, skinless, boneless muscle tissue from above the lateral line) were collected from sport-fish species of various edible sizes (walleye, northern pike, lake trout, brook trout, and smallmouth bass [Micropterus dolomieu] ) and frozen at $-20^{\circ} \mathrm{C}$ until further analysis (Sandstron et al. 2011). Frozen fish tissue samples were sent to the OMOE Sport Fish and Biomonitoring Unit lab in Toronto, Ontario, for total mercury analysis by cold vapour-flameless atomic absorption spectroscopy at an accredited lab certified by the Canadian Association for Laboratory Accreditation. Total mercury (THg ppm wet weight (w.w.)) was determined for each fish following standard OMOE protocols (OMOE 2006). Ageing materials were sampled from individual fish according to protocols by Mann (2004). Structures were analyzed and interpreted at the OMNR's Regional Ageing Laboratory in Dryden, Ontario (Mann 2004).

## Standardizing Mercury in Fish Tissue

In order to have comparable contaminant information among lakes, total mercury concentrations in fish of a standard length were used for inter-lake comparisons of fish populations. The THg concentrations standardized to a mean total length exhibit important interlake variability for all species of fish even within the same region (Tremblay et al. 1998; Simoneau et al. 2005). The fish dataset, compiled from OMNR and OMOE databases, contained information on 2250 walleye ( 121 lakes), 1191 northern pike ( 106 lakes), 940 lake trout ( 60 lakes), 241 brook trout ( 18 lakes), and 518 smallmouth bass ( 37 lakes) (see Appendix D: Table D.2). Standardized lengths were chosen based on the OMOE standard lengths calculated from
the population size distributions of various fish species (Gewurtz et al. 2010) as well as from analysis of the mean total length of each species in the dataset (Appendix D: Figure D.1). Standards for brook trout and smallmouth bass were based on the population means from this dataset alone, as no standard was available from the OMOE. The standard total lengths by species were: walleye ( 500 mm ), northern pike ( 650 mm ), lake trout ( 600 mm ), brook trout (300 $\mathrm{mm})$, and smallmouth bass $(400 \mathrm{~mm})$. The standard mercury level $(\mu \mathrm{g} / \mathrm{g}$ wet weight of skinless boneless dorsal muscle $=$ ppm w.w.) for each fish population was calculated by using the power function

$$
\text { Equation 1. } \quad\left(\mathrm{C}_{\mathrm{L}}=\mathrm{aL}^{\mathrm{b}}\right)=\left(\log \mathrm{C}_{\mathrm{L}}=\log (\mathrm{a})+\mathrm{b}^{*} \log (\mathrm{~L})\right)
$$

$\mathrm{C}_{\mathrm{L}}$ is the concentration at length $\mathrm{L}(\mathrm{cm})$, $a$ is a constant, and $b$ is the power of the relationship between concentration and length on fish data, specific to one netting season with more than 3 data points, (Gewurtz et al. 2011) (Appendix D). The power-series (log-log) regression is used by the OMOE Sports Fish Contaminant Monitoring Program to calculate the relationship between contaminant concentration and length (Gewurtz et al. 2011). The fit of the relationship between fish total mercury concentration and total length was evaluated in order to determine the most appropriate model. Compared to the polynomial or linear regression, the log-log regression was the most appropriate model used to describe the relationship between mercury concentration and length (Gewurtz et al. 2011).

## Statistical Procedure

A correlation analysis was performed and inter-correlated variables (Pearson correlation coefficients ( r ) $>0.9$ ) were removed from the dataset in order to minimize multi-collinearity in ordination analyses. Nonmetric multidimensional scaling ordinations were used to examine the association between spatial attributes of the waterbody catchment, lake chemistry characteristics and total mercury concentrations for each species. Nonmetric multidimensional scaling is considered the most robust unconstrained ordination for use in community ecology as it makes few assumptions about the nature of the data (Minchin 1987; Holland 2008). Ordinations were performed in R (version 2.13.1) using the package vegan (version 2.0-2) which was designed for
ecological data analysis (Okasanen 2011). The same set of waterbody catchment and lake scale variables were used in ordinations of lakes and watersheds for each species. A subset of the 243 lakes was included in separate ordinations characterized by fish species and lakes without water quality data were excluded from the sample set (walleye $=107$ lakes, northern pike $=97$ lakes, lake trout $=54$ lakes, smallmouth bass $=35$ lakes, brook trout $=15$ lakes). Ordination analysis was also used to show the associations between the physical watershed and lake scale variables and their relationship with spring lake water chemistry variables.

Dissimilarity was measured as Bray-Curtis distances and random starting configurations (the maximum number is given by trymax) were used to reach a stable solution. The metaMDS function uses the monoMDS function which implements Kruskal's NMDS using monotone regression and weak treatment of ties (Kruskal 1964 a, b). The dimensionality of each ordination was determined using the scree plot of stress vs. dimensionality for each individual ordination. The goodness of fit was determined by the non-metric $\mathrm{r}^{2}$ value based on stress $S$ from the Shepard plot. Once the dimensionality was determined, the data were fitted into the dimensions with no hidden axes of variation. In order to avoid local minima (trymax=1000), random starting configurations were used until a convergent solution was reached. Scores were scaled, centred and rotated. A square root transformation and Wisconsin double standardization of the data matrix was used to improve the results of the ordination. The final solutions were compared by using Procrustes analysis (root mean squared error [rmse]). The solution was regarded as a convergent stable solution if two solutions were very similar in their Procrustes rmse and the largest residual was very small.

Based on the ordinations, individual lake or waterbody catchment scale variables that were associated with THg concentrations in fish were selected for further analyses. The correlations (r) between watershed scale variables, lake scale variables, and standardized fish THg concentrations were examined to further refine the subset of variables for further analyses. The relationship between selected lake chemistry parameters and fish THg concentrations for all species was examined with a general linear model analysis. Similarly, the relationships between harvesting or natural disturbance and fish THg concentrations for all species were examined using general linear model analyses. To determine if the relationship between THg concentrations and lake chemistry or waterbody catchment scale parameters differed among the species of fish an analysis of covariance (ANCOVA) was used.

Three categories of contamination for mercury concentrations in fish tissue were created to summarize the variability in mercury concentrations for further analysis of the associations between fish standardized mercury concentrations and watershed characteristics for the five species of fish. The low category is based on the Canadian standard for the commercial sale of fish and represents the group of lakes with less than 0.5 ppm w.w. THg in the standard fish. The moderate category represents lakes having standard fish of intermediate contamination ranging in concentrations from 0.5 to 1.0 ppm w.w. THg. The elevated category represents lakes with standard fish having concentrations that exceed the American FDA "action level" of 1.0 ppm w.w. THg for commercially sold fish. The difference in waterbody catchment disturbance from 1990-2009 and 2000-2009 or wetland percentages were compared among the three categories of contamination. Differences among groups were evaluated for each species with the nonparametric Kruskal-Wallis analysis of variance (ANOVA).

The relationship between fish THg concentrations with the lake to waterbody catchment area ratio or lake surface area was determined with general linear model analysis. Analysis of covariance (ANCOVA) was used to determine if the relationship between fish THg concentrations with either the lake to waterbody catchment area ratio or lake size differed according to species. Lake surface area was divided into 5 size classes to summarize the variability in lake size in order to make additional comparisons to fish mercury concentrations among lakes. Differences in fish THg concentrations related to lake size were evaluated among the five lake surface area classes with the non-parametric Kruskal-Wallis analysis of variance (ANOVA) and Dunn's pair-wise comparison test.

## Results

## Catchment Analysis

Waterbody catchment area for study lakes ranged from 69 ha (Beak Lake) to 104,362 ha (Lake Nipissing) (mean $5362 \pm 9573$ ha, $\mathrm{n}=243$ ). Surface area ranged from 7 ha (Beak Lake) to 72861 ha (Lake Nipissing) (1739 $\pm 5182$ ha). Lake surface area/waterbody catchment area ratio ranged from 0.01 (Bear Lake, a small lake with a large direct drainage area) to 0.70 (Lake Nipissing, a large lake with a relatively small direct drainage area). Spatial waterbody catchment variables were summarized for each lake in Appendix B (Table B.1). Between 2000 and 2009, forest harvesting ranged from $0 \%$ to $40 \%$ of the total waterbody catchment area and natural forest disturbance ranged from $0 \%$ to $100 \%$ of the total waterbody catchment area for the 243 lakes used in this study. In total, 138 lakes (approximately 57\%) had forest harvesting in the catchment area and 42 lakes (approximately 17\%) had natural disturbance events between 2000 and 2009. The percentage cover of wetlands was also variable, covering $0 \%$ to $34.9 \%$ of the total waterbody catchment area.

## Fish Mercury Concentrations

Species specific ranges in THg concentration, based on fish of standardized lengths are presented in Figure 1.3. The standardized fish THg concentrations are variable among species within and among lakes (Appendix D: Table D.2). On average, the length-standardized mercury THg concentration in walleye (mean $0.78 \pm 0.36 \mathrm{ppm} w . w$. for TLEN $=500 \mathrm{~mm}$ ), northern pike (mean 0.73. $\pm 0.39 \mathrm{ppm} \mathrm{w} . \mathrm{w}$ for TLEN $=650 \mathrm{~mm}$ ) and lake trout (mean $0.66 \pm 0.52 \mathrm{ppm} \mathrm{w} . \mathrm{w}$. for TLEN $=600 \mathrm{~mm}$ ) exceeded the Canadian standard of 0.5 ppm w.w. THg in fish tissue.

Figure 1.3 Boxplot of standardized total THg concentrations in fish tissue (ppm w.w.) according to species. Horizontal black lines represent the median, the boxes indicate the inter-quartile range (IQR) and the whiskers represent 1.5 times the IQR from the first and third quartile, hollow circles represent data outside of the $\left(Q 1-1.5^{*} \mathrm{IQR}, \mathrm{Q} 3+1.5^{*} \mathrm{IQR}\right)$, black triangle represents mean, n is number of lakes

## Multivariate Analysis of the Associations between Fish THg concentrations and Lake and Catchment Scale Characteristics

## Walleye THg Associations with Catchment and Water Chemistry Characteristics

The subset of 107 study lakes that contained walleye varied in their waterbody catchment and water chemistry characteristics but showed no clear groupings of different lake types. Waterbody catchments ranged from those dominated by bedrock to catchments with higher proportions of glaciolacutrine and morainal deposits (axis 1, Figure 1.4). Lakes with higher amounts of DOC and nutrients (total Kjeldahl nitrogen (NNTKUR) and total phosphorus (PPUT)) tended to have catchments with higher values for stream density ( $\mathrm{km} / \mathrm{ha}$ ), a greater proportion of catchment area classified as organic surficial material, and wetland areas and were distinct from lakes with high secchi depth, large lake surface area and large waterbody catchment area (axis 2, Figure 1.4). Overall, the variability summarized by the ordination is consistent with expectations of inland lakes of northern Ontario which range from small dystrophic lakes rich in humic materials where the majority of organic matter originates from the watershed (allochthonous) to large clear oligotrophic lakes. The vast amount (94.5\%) of among lake variability is captured by this 2-dimensional solution. The fit of the ordination is satisfactory as a convergent solution was found after 365 iterations where the final stress $=0.234$ (procrustes: rmse 0.0012 , max resid 0.0085 ).

Total mercury in walleye was only weakly associated with waterbody catchment and lake water chemistry characteristics. Only $5.4 \%$ of the variability in walleye THg concentration was explained by the ordination $\left(\mathrm{r}^{2}=0.054, \mathrm{p}=0.066\right)$, however, the trend in walleye THg concentration illustrated by the vector (Figure 1.4) was consistent with predicted patterns. As indicated by the correlation vector in the ordination, walleye THg concentrations were positively associated with the proportion of surficial material classified as organic matter within the waterbody catchment, stream density ( $\mathrm{km} / \mathrm{ha}$ ), wetland area, DOC, and nutrients; characteristics of small dystrophic lakes. There was also a positive association between the walleye THg and forest harvest (2000-2009 and 1990-2000) and road density ( $\mathrm{km} / \mathrm{ha}$ ). Conversely, walleye THg concentrations were negatively associated with lake volume, lake surface area, max depth of the water column, secchi depth, sulfate concentrations, the lake:catchment area ratio, and waterbody catchment area.

Figure 1.4. Non-metric multidimensional scaling ordination based on catchment and water chemistry characteristics of 107 walleye lakes. Blue squares represent individual lakes and open circles represent the variables used in the ordination. The correlation ( $r=0.23$ ) between lake characteristics and walleye $\mathbf{T H g}$ concentrations is illustrated by the vector.

## Northern Pike THg Associations with Catchment and Water Chemistry Characteristics

Similar to the lakes containing walleye, the 97 lakes that contained northern pike varied according to waterbody catchment and lake scale variables and no distinct clustering of different lake types was apparent. Surficial geology appears to influence major differences among lakes, as the catchments range from bedrock to finer glaciofluvial and glaciolacustrine deposits (Axis 1, Figure 1.5). Lake water alkalinity and base cation (magnesium ( $\mathrm{Mg}^{2+}$ ), calcium $\left(\mathrm{Ca}^{2+}\right)$, potassium $\left(\mathrm{K}^{+}\right)$, and sodium $\left(\mathrm{Na}^{+}\right)$) concentrations were positively associated with harvesting disturbance from 2000-2009 and road disturbance within the waterbody catchment and negatively associated with lake surface area (Figure 1.5). Approximately $94 \%$ of the differences among sites are explained by the 2 -dimensional solution. A convergent solution was found after 260 iterations where the final stress $=0.245$ (procrustes: rmse 0.0007 , max resid 0.0036). This ordination is suitable for interpretation as the non-metric $\mathrm{r}^{2}$ and final stress value are satisfactory.

Northern pike THg concentrations were very weakly associated with waterbody catchment and lake scale characteristics with only $1.2 \%$ of the variability in northern pike THg concentration explained by the ordination ( $\mathrm{r} 2=0.012, \mathrm{p}=0.579$ ). As indicated by the correlation vector in the ordination, northern pike THg concentrations showed positive associations with base cation concentrations, alkalinity, road density ( $\mathrm{km} / \mathrm{ha}$ ), and the proportion of the waterbody catchment classified as glaciofluvial and glaciolacustrine surficial geology. Northern pike THg concentrations were negatively associated with the lake:catchment area ratio, lake surface area, and waterbody catchment area. There was no apparent association between northern pike THg concentrations and lake water DOC concentration, nutrients, or secchi depth .

Figure 1.5. Non-metric multidimensional scaling ordination based on waterbody catchment and lake scale characteristics of $\mathbf{9 7}$ northern pike lakes. Blue squares represent individual lakes and open circles represent the variables used in the ordination. The correlation $(r=0.11)$ between lake characteristics and northern pike THg concentrations is illustrated by the vector.

The 54 lakes containing lake trout were relatively closely grouped in the ordination and are fairly similar in terms of waterbody catchment and lake scale characteristics (Figure 1.6). Similar to the subset of lakes containing walleye, lakes containing lake trout range from large clear lakes to small stained lakes (axis 2, Figure 1.6). Approximately $96.2 \%$ of the differences among lakes were explained by the 2 -dimensional ordination solution. A convergent solution was found after 113 iterations where the final stress $=0.1942$ (rmse 0.0013, max resid 0.0061).

Lake trout THg concentrations were also very weakly associated with waterbody catchment and lake scale variables. Only $1.0 \%$ of the variability in lake trout THg concentration was explained by the variables used in the ordination ( $\mathrm{r}^{2}=0.01, \mathrm{p}=0.778$ ). Interpreting the relationship between fish THg concentrations with waterbody catchment and lake scale variables is risky since lake trout mercury concentrations were not significantly correlated to the ordination. However, lake trout THg concentrations showed positive associations with harvesting during the years 2000-2009 and 1990-2000, the amount of wetlands within the waterbody catchment area, the proportion of the surficial geology classified as organic material, stream density ( $\mathrm{km} / \mathrm{ha}$ ), reactive silicate (SIO3UR), nutrients, DOC, and the percentage of glaciofluvial and glaciolacustrine surficial geology within the waterbody catchment. Lake trout THg concentrations show negative associations with base cations, sulfate, secchi depth, the waterbody catchment area, lake surface area, and the lake:catchment area ratio. Lake water pH does not appear to be associated with lake trout THg concentrations.

Figure 1.6. Non-metric multidimensional scaling ordination based on waterbody catchment and lake scale characteristics of 54 lake trout lakes. Blue squares represent individual lakes and open circles represent the variables used in the ordination. The correlation ( $r=0.1$ ) between lake characteristics and lake trout $\mathbf{T H g}$ concentrations is illustrated by the vector.

## Smallmouth Bass THg Associations with Catchment and Water Chemistry Characteristics

The 35 lakes containing smallmouth bass were more similar to each other based on waterbody catchment and lake scale characteristics compared to the preceding groups of lakes. Similar to the groups of lakes containing walleye or lake trout, lakes containing smallmouth bass range from large clear lakes to small stained lakes (axis 2, Figure 1.7). Forest harvesting and natural disturbance variables are distinctly separate from the other lake and waterbody catchment scale variables and these occurrences were associated with only a few lakes. Approximately $96.7 \%$ of the differences among sites were explained by the 2-dimensional solution. A convergent solution was found after 15 iterations where the final stress $=0.1807$ (procrustes: rmse 0.0003 , max resid 0.0008 ).

Waterbody catchment and lake variables explained $37.7 \%$ of the variability in smallmouth bass total THg concentration ( $\mathrm{r}^{2}=0.377, \mathrm{p}=0.001$ ). Smallmouth bass THg concentrations are not closely associated with harvesting disturbance within the waterbody catchment between the two time intervals of 1990-2000 and 2000-2009 (Figure 1.7). However, natural disturbance within these two time periods appears to be more clearly associated with fish THg concentrations. There is a positive association with THg and the percentage of morainal and glaciolacustrine surfical geology. As indicated by the correlation vector in the ordination, smallmouth bass THg concentrations show negative associations with sulfate concentration, secchi depth, the percentage of bedrock surficial geology, lake surface area, waterbody catchment area, the lake:catchment area ratio. No observed association exists between lake water pH and smallmouth bass THg concentrations.

Figure 1.7. Non-metric multidimensional scaling ordination based on the waterbody catchment and lake scale characteristics of 35 lakes containing smallmouth bass. Blue squares represent individual lakes and open circles represent the variables used in the ordination. The correlation $(r=0.61)$ between lake characteristics and smallmouth bass $\mathbf{T H g}$ concentrations is illustrated by the vector.

The 15 brook trout lakes were very similar in waterbody catchment and lake scale characteristics and are closely grouped in the ordination with no clear pattern of association with any environmental variables (Figure 1.8). The relationships among variables noted in previous groups of lakes are not as apparent for this dataset. The 2-dimensional ordination explains $98 \%$ of the differences among sites. A convergent solution was found after 10 iterations where the final stress $=0.1412$ (procrustes: rmse 0.0024 , max resid 0.0068).

There was a significant relationship between brook trout THg concentrations and waterbody catchment and lake scale variables $\left(\mathrm{r}^{2}=0.535, \mathrm{p}=0.011\right)$. As indicated by the correlation vector in the ordination, brook trout THg concentrations showed positive associations with forest harvesting and natural disturbance which occurred between 1990-2000. The amount of wetlands within the waterbody catchment, road density ( $\mathrm{km} / \mathrm{ha}$ ), DOC, and nutrients are also positively associated with brook trout THg concentrations. The lake:catchment area ratio and secchi depth are negatively associated with THg concentrations in brook trout. There is no apparent association between lake water pH and brook trout THg concentrations.

Figure 1.8. Non-metric multidimensional scaling ordination based on the waterbody catchment and lake scale characteristics for 15 lakes. Blue squares represent lakes. Blue squares represent individual lakes and open circles represent the variables used in the ordination. The correlation $(r=0.73)$ between lake characteristics and brook trout $\mathbf{T H g}$ concentrations is illustrated by the vector.

## Multivariate Associations between Water Chemistry and Waterbody Catchment and Lake Scale Characteristics

A NMDS ordination was used to assess the associations between waterbody catchment and lake scale factors and their relationship to spring lake water chemistry. No distinct grouping of lake type exists and the 175 lakes differ mainly by surficial geology characteristics of the waterbody catchments. The HCAT average decadal summer temperature and average decadal precipitation from 1990-1999 and 2000-2009 were not variable among lakes. This ordination summarized approximately $95.8 \%$ of among lake variability with the 2-dimensional solution. A convergent solution was found after 103 iterations where the final stress $=0.2143$ (procrustes: rmse 0.0016 , max resid 0.0089 ).

Nutrients, reactive silicate (SIO3UR), dissolved organic carbon, and base cations were correlated vectors that were positively associated with higher percentages of wetlands, finer glacial sediments and organic matter dominating the surficial geology of the waterbody catchment as well as disturbance from forest harvesting and roads ( $\mathrm{p}<0.05$, Figure 1.9). Dissolved organic carbon and total Kjeldhal nitrogen concentrations were the water chemistry variables with the strongest association with the variables used in the ordination $\left(\mathrm{r}^{2}=0.28\right.$, $p=0.001$ and $r^{2}=0.27, p=0.001$ respectively). Forest harvesting disturbance during the 1999-2000 decade is distinctly separate from the 2000-2009 decade with respect to water chemistry as indicated by the distance between variables in ordination space. Secchi depth was positively associated with the lake:catchment area ratio and stream density ( $\mathrm{km} / \mathrm{ha}$ ) and was significantly related to the ordination $\left(r^{2}=0.18, p=0.001\right)$. Sulfate concentrations showed a weaker correlation to the ordination (SS04UR: $\mathrm{r}^{2}=0.05, \mathrm{p}=0.015$ ) but were closely associated with the percentage of bedrock within the waterbody catchment. Alkalinity ( $\mathrm{r}^{2}=0.06, \mathrm{p}=0.003$ ) and base cation concentrations (CAUT: $r^{2}=0.05, p=0.007$; KKUT: $r^{2}=0.12, p=0.001$; MGUT: $r^{2}=0.09, p=0.001$; NAUT: $r^{2}=0.06, p=0.006$ ) were correlated to one another and showed weak positive relationships with the percentage surficial sediments classified as organic material and disturbance within the waterbody catchment. The HCAT average decadal summer temperature and average decadal precipitation from 1990-1999 and 2000-2009 had no apparent associations with the lake water chemistry variables.

Figure 1.9. Non-metric multidimensional scaling ordination showing the associations between waterbody catchment features and correlated lake chemistry characteristics ( $\mathrm{n}=\mathbf{1 7 5}$ lakes). Blue squares represent individual lakes and open circles represent the variables used in the ordination. The correlations between lake characteristics and water chemistry variables are illustrated by the vectors.

## Univariate Relationships between Waterbody Catchment Scale or Lake Chemistry with Fish Mercury Concentrations

The correlations between THg concentrations in all fish species and characteristics of the waterbody catchment and lake which appeared most influential in the ordination analyses are shown in Table 1.3. The strongest and most consistent correlation was between DOC and THg concentrations in all species. Dissolved organic carbon concentrations were significantly positively related to THg concentrations $\left(F_{(1,314)}=21.596, p<0.0001\right)$. and the relationship between fish THg concentrations and DOC concentrations was the same for the 5 species of fish examined as indicated by the ANCOVA analysis of the homogeneity of regression (intercept: $F$ $(4,314)=0.684, p=0.603$; slopes: $F_{(4,314)}=0.463, p=0.763$ ) in the subset of 175 lakes (Figure 1.10 a).

Secchi depth $(3.28 \pm 1.79 \mathrm{~m})$ was consistently correlated to THg concentrations for all fish species (Table 3) and is a negatively associated covariate of DOC ( $7.69 \pm 3.74 \mathrm{mg} / \mathrm{L}$ ) ( $\mathrm{r}=-$ $0.736, \mathrm{p}=0.0001$ ). Secchi depth was significantly negatively related to THg concentrations $\mathrm{F}_{(1,}$ 313) $=21.67, p<0.0001)$. The relationship between fish THg concentrations and secchi depth was not the same for the 5 species of fish examined as indicated by the ANCOVA analysis of the homogeneity of regression (intercept: $F_{(4,313)}=3.208, p=0.013$; slopes: $F_{(4,313)}=0.776$, $p=0.542$ ). In this particular analysis, the intercept is significantly different amongst the 5 species of fish due to differences in the mean mercury concentrations (walleye $0.78 \pm 0.36 \mathrm{ppm}$ w.w., smallmouth bass $0.47 \pm 0.19 \mathrm{ppm}$ w.w., northern pike $0.73 \pm 0.39 \mathrm{ppm}$ w.w., lake trout $0.66 \pm$ 0.52 ppm w.w., and brook trout $0.26 \pm 0.16 \mathrm{ppm}$ w.w.).

The DOC concentration in lake water was significantly positively correlated with the percentage of wetland area in the catchment $\left(r^{2}=0.116, p<0.001\right)$ but was not significantly related to forest harvesting disturbance ( $\mathrm{r}^{2}=0.014, \mathrm{p}=0.125$ ) (Figure $1.11 \mathrm{a}, \mathrm{b}$ ). The percentage of wetland area in a catchment was positively correlated to true colour ( $\mathrm{r}=0.309, \mathrm{p}<0.001$ ), secchi depth ( $\mathrm{r}=-0.268, \mathrm{p}<0.001$ ), phosphorus $(\mathrm{r}=0.245, \mathrm{p}<0.01$ ), total Kjeldahl nitrogen ( $\mathrm{r}=0.300$, $\mathrm{p}<0.001$ ), reactive silicate ( $\mathrm{r}=0.155, \mathrm{p}<0.05$ ), proportion of organic surficial material within the waterbody catchment $(\mathrm{r}=0.387, \mathrm{p}<0.001$ ) and negatively correlated to secchi depth ( $\mathrm{r}=-$ $0.268, \mathrm{p}<0.001$ ).

Further analysis of other water chemistry variables showed weak relationships with fish mercury concentrations. Total Kjeldahl nitrogen ( $323.3 \pm 103.5 \mu \mathrm{~g} / \mathrm{L}$ ) and total phosphorus (9.2
$\pm 5.2 \mu \mathrm{~g} / \mathrm{L}$ ) in lake water were correlated to THg concentrations in some but not all species of fish (Figure 1.12). When species were analysed separately, total Kjeldahl nitrogen was positively related to fish THg concentrations in brook trout ( $\mathrm{r}=0.526, \mathrm{p}<0.05$ ), lake trout ( $\mathrm{r}=0.278, \mathrm{p}$ $<0.05$ ), northern pike ( $\mathrm{r}=0.245, \mathrm{p}<0.05$ ), and smallmouth bass ( $\mathrm{r}=0.485, \mathrm{p}<0.01$ ) but not walleye. Total phosphorus was only significantly related to fish THg concentrations in brook trout ( $\mathrm{r}=0.608, \mathrm{p}<0.05$ ) and northern pike ( $\mathrm{r}=0.309, \mathrm{p}<0.01$ ). Overall, fish THg concentrations were significantly related to total Kjeldahl nitrogen $\left(F_{(1,314)}=7.297\right.$, $\left.p=0.007\right)$ but not to total phosphorus $\left(F_{(1,314)}=2.196, p=0.139\right)$ concentrations in lake water (Figure 1.12). The relationship between fish THg concentration and total Kjeldahl nitrogen concentration in lake water does not differ significantly as a function of species (ANCOVA analysis of the homogeneity of regression intercept: $\left.F_{(4,314)}=2.017, p=0.092\right) ;$ slopes: $F_{(4,314)}=1.298$, $p=0.271)$ ). Lake water $\mathrm{pH}(7.00 \pm 0.40)$ and sulfate concentrations ( $3.64 \pm 4.31 \mathrm{mg} / \mathrm{L}$ ) did not span across a wide range values. Fish THg concentrations were not significantly related to lake water $\mathrm{pH}\left(F_{(1,313)}=2.477, p=0.117\right)$ nor sulfate concentrations $\left(F_{(1,314)}=0.409, p=0.523\right)$ (Figure 1.13).

## Forest Harvesting and Natural Disturbance Associations with Fish Mercury Concentrations

For all species, the THg concentration in fish from lakes with waterbody catchment areas affected by forest harvesting or natural disturbance fell within the observed range of THg concentrations in fish from lakes with no catchment disturbance (Figs. 1.14-1.17). Fish THg concentrations were not significantly related to percent area of the catchment disturbed by forest harvesting between 2000 and 2009 or to disturbance occurring between 1990 and 2009 (Figure 1.14: $F_{(1,334)}=1.683, p=0.195$, and Figure 1.15: $F_{(1,334)}=2.257, p=0.134$ respectively). Similarly, fish THg concentrations were not related to the percentage of the waterbody catchment area disturbed by natural disturbance events during the 2000-2009 or 1990-2009 time periods (Figure 1.16: $F_{(1,335)}=0.022, p=0.881$, and Figure 1.17: $F_{(1,335)}=0.463, p=0.497$ respectively).

The percentage of waterbody catchment area disturbed by harvesting and natural disturbance was highly variable among the different lakes (Table 1.4). Harvesting disturbance occurred within the waterbody catchment area of 81 walleye lakes ( $76 \%$ of sites), 65 northern pike lakes ( $67 \%$ of sites), 35 lake trout lakes ( $65 \%$ of sites), 5 brook trout lakes ( $33 \%$ of sites) and 21 smallmouth bass lakes ( $60 \%$ of sites). Natural disturbance occurring between 2000-2009 ranged from $0 \%$ to $100 \%$ of the waterbody catchment area for all sites, however the majority of lakes had very little natural disturbance. The waterbody catchment area of 83 walleye lakes ( $78 \%$ of sites), 75 northern pike lakes ( $77 \%$ of sites), 49 lake trout lakes ( $91 \%$ of sites), 15 brook trout lakes ( $100 \%$ of sites), and 28 smallmouth bass lakes ( $80 \%$ of sites) had no natural disturbance.

Table 1.4. Percentage of the waterbody catchment area disturbed by forest harvesting and natural disturbance events during the years 2000-2009 for groups of lakes organized by species presence.

## Relationships between Wetlands and Fish Mercury Concentrations

The percentage of waterbody catchment area with wetlands was variable among the different lakes (Table 1.5). The THg concentration for all species of fish from lakes with waterbody catchment areas containing wetlands was also within the observed range of THg concentrations in fish from lakes with very few to no associated wetlands (Figure 1.18). Fish THg concentrations were not significantly related to percent area of the waterbody catchment having wetlands (Figure 1.18: $F_{(1,334)}=2.380, p=0.124$ ).

## Waterbody Catchment Associations with Categories of Contamination

Waterbody catchment characteristics were not significantly different amongst the three groups of lakes classified by the standard mercury concentration in walleye. The percentage of waterbody catchment disturbed by forest harvesting between 2000-2009 or 1990-2009 did not differ significantly among the mercury contamination categories of walleye (Figure 1.19: 2000$2009(\mathrm{H}=0.936, \mathrm{df}=2, \mathrm{p}=0.626)$ or Figure 1.20: 1990-2009 $(\mathrm{H}=0.765, \mathrm{df}=2, \mathrm{p}=0.730)$ ). Similarly, the percentage of natural disturbance occurring in waterbody catchments between 2000-2009 or 1990-2009 did not differ significantly among mercury contamination categories of walleye (2000-2009 $(\mathrm{H}=5.540, \mathrm{df}=2, \mathrm{p}=0.063)$ Figure 1.21 or $1990-2009(\mathrm{H}=1.237, \mathrm{df}=2, \mathrm{p}=$ 0.539) Figure 1.22). The percentage of wetland area of the total waterbody catchment was not significantly different between the categories of fish mercury contamination $(\mathrm{H}=0.186, \mathrm{df}=2, \mathrm{p}=$ 0.911; Figure 1.23). The same analysis conducted on lakes containing northern pike, lake trout, and smallmouth bass showed similar trends with no significant difference among the categories of contamination.

Figure 1.19. The comparison between walleye $\mathbf{T H g}$ contamination categories and percentage of forest harvesting disturbance within the waterbody catchment from the years of 2000-2009. The horizontal black line represents the median, the boxes indicate the inter-quartile range (IQR) and the whiskers represent 1.5 times the IQR from the first and third quartile, hollow circles represent data outside of the (Q1-1.5* IQR, Q3 $+1.5^{*} \mathrm{IQR}$ ). The mean is represented by the black triangle and the number of samples ( n ) represents the number of lakes in that category.

## Lake Size and Lake to Waterbody Catchment Area Ratio Influences

Overall, fish THg concentrations were significantly related the ratio of lake area within the waterbody catchment (Figure 1.24: $F_{(1,332)}=8.074, p=0.005$ ). The relationship between fish THg concentration and the lake to waterbody catchment ratio does not differ significantly as a function of species (ANCOVA analysis of the homogeneity of regression (intercept: $F_{(4,332)}=$ $1.203, p=0.309$; slopes: $\left.F_{(4,332)}=0.314, p=0.868\right)$ ).

Fish THg concentrations tended to be negatively associated with lake area but the relationship was variable among species and was not significant (Figure 1.25: $F_{(1,332)}=0.088, p=$ 0.766 ). When species were examined separately, all species showed a negative relationship between THg levels and lakes size, analysed in size classes defined by surface area. Northern pike $(H=9.671, \mathrm{df}=4, \mathrm{p}=0.046)$ and lake trout $(\mathrm{H}=10.778, \mathrm{df}=4, \mathrm{p}=0.029)$ had significantly higher standardized THg concentrations in small (size bin 1: < 100 ha ) lakes (Dunn's pairwise comparison, $\mathrm{p}<0.05$, Figure 1.27 and Figure 1.28 respectively). Walleye ( $\mathrm{H}=3.034$, df=4, $\mathrm{p}=0.552$ ), brook trout $(\mathrm{H}=0.009, \mathrm{df}=4, \mathrm{p}=0.925)$ and smallmouth bass $(\mathrm{H}=3.949, \mathrm{df}=3, \mathrm{p}=0.267)$ also showed a negative relationship with lake size class although THg differences among the size classes were not significant as indicated by the non-parametric Kruskal-Wallis test (Figure 1.26, Figure 1.29, and Figure 1.30 respectively).

Figure 1.24. The relationship between the lake to waterbody catchment surface area ratio and $\mathbf{T H g}$ concentrations (ppm w.w.) according to species (brook trout: $\mathbf{n = 1 8}$, lake trout: $\mathbf{n = 6 0}$, northern pike: $\mathbf{n = 1 0 6}$, smallmouth bass: $\mathbf{n = 3 7}$, walleye: $\mathbf{n = 1 2 1}$ ).

Figure 1.25. The relationship between fish $\mathbf{T H g}$ concentration (ppm w.w.) and lake area according to species (brook trout: $\mathbf{n = 1 8}$, lake trout: $\mathbf{n = 6 0}$, northern pike: $\mathbf{n}=106$, smallmouth bass: $\mathbf{n}=37$, walleye: $\mathbf{n = 1 2 1}$ ).

Figure 1.26. THg concentrations of walleye grouped according to lake surface area size bin category (Bin 1 [<100 ha]: $\mathbf{n = 1}$, Bin 2 [100-500 ha]: n=29, Bin 3 [500-1500 ha]: n=39, Bin 4 [1500-5000 ha]: $n=40$, Bin 5 [ $>5000 \mathrm{ha}]: n=13$ ). The box indicates the inter-quartile range (IQR), the dark horizontal line indicates the median and the "whiskers" extending above and below the box indicate 1.5 times the IQR. Outliers are represented as circles and extreme values (greater than 3 times the IQR) are indicated by asterisks.

Figure 1.27. THg concentrations of northern pike grouped according to lake surface area size bin category (Bin 1 [ $<100$ ha]: $n=5$, Bin 2 [100-500 ha]: $n=29$, Bin 3 [500-1500 ha]: $n=35$, Bin 4 [1500-5000 ha]: $\mathbf{n = 2 9}$, Bin 5 [ $>5000 \mathrm{ha}$ ]: $\mathbf{n = 8}$ ). Details of the plot are the same as the previous Figure 1.26.

Figure 1.28. Figure 1.30. THg concentrations of smallmouth bass grouped according to lake surface area size bin category (Bin 2 [100-500 ha]: $n=7$, Bin 3 [500-1500 ha]: n=12, Bin 4 [1500-5000 ha]: n=16, Bin 5 [ $>5000$ ha]: $\mathrm{n}=2$ ). Details of the plot are the same as the previous Figure 1.26.

## Discussion

For the majority of lakes in this study, mercury contamination in fish is a significant problem as the average total mercury concentration for a standard sized lake trout, northern pike, or walleye exceeded Health Canada's guideline of $0.5 \mathrm{ppm} w . w$. THg content in fish (Appendix D: Table D.2). All species of fish are highly variable in terms of THg concentrations among lakes which may differ by an order of magnitude or more between adjacent lakes (Figure 1.3). These results are comparable to the James Bay region of Quebec where length-standardized THg concentrations in fish varied by factors of 3-4 between neighbouring lakes (Schetagne and Verdon 1999). Similarly, populations of walleyes in lakes of four different regions of Quebec (Saint Lawrence Valley, Chibougamau, Abitibi, and Témiscamingue) standardized to length of 350 mm ranged from 0.17 to 0.79 ppm (Simoneau et al. 2005).

Overall, fish mercury concentrations for the different species were weakly correlated to the waterbody catchment and lake scale factors. The associations between THg concentrations of different fish species with waterbody catchment or lake scale environmental factors showed similar trends among a wide variety of lakes occurring in northern Ontario (Figs. 2.4-2.8). Although no apparent grouping of lakes existed based on their waterbody catchment or lake characteristics, the surficial geology of the waterbody catchment was important for distinguishing the differences among lakes which varied in terms of water chemistry and ranged from small darkly stained dystrophic lakes to larger clear oligotrophic lakes. Common to all species, the highest mercury concentrations in fish were generally found in small darkly stained lakes having recent forest harvesting disturbance and greater percentages of wetlands and organic material within the waterbody catchment. The density of roads ( $\mathrm{km} / \mathrm{ha}$ ) was also associated with the percentage of forest harvesting disturbance as would be expected for many of the waterbody catchments where forest harvesting disturbance was the single anthropogenic disturbance present. Water chemistry parameters such as DOC and total phosphorus were associated with one another and positively associated with fish mercury concentrations.

The ordinations (Figure 1.4 and Figure 1.5) for lakes containing walleye or northern pike have high stress values $(>0.2)$ which may lead to a misinterpretation of the
results. Kruskal (1964 a, b) and later authors suggested that the stress values in NMDS be used as guidelines for interpreting ecological data. A stress value $>0.2$ is considered poor and the ordination may not reliably summarize variability in the data set resulting in misleading interpretations. However, stress increases with the number of variables and the number of samples and a larger dataset will result in a higher stress value (Holland 2008). Higher stress values for the walleye and northern pike ordinations could be attributed to larger sample sizes ( $\mathrm{n}=107$ for walleye, and $\mathrm{n}=97$ for northern pike). The northern pike and walleye datasets are largely the same as both species coexist in 70 lakes which contributes to the similar associations observed between watershed and lake scale characteristics among the ordinations of lakes containing walleye or northern pike.

The number of lakes available for analysis was also limited for some species. The number of lakes with smallmouth bass was relatively small and the ordination violates the rule for adequate sample size where the number of variables used in the ordination should be less than five times the number of sites (Tabachnik and Fidell 1989). Likewise, the number of brook trout lakes $(\mathrm{n}=15)$ is less than the number of variables ( 31 different waterbody and lake scale characteristics) used in the ordination, violating the rule for adequate sample size in ordination analysis. Therefore, there is a possibility that the interpretation of these ordinations may be misleading and the small sample size may misrepresent the associations between sites and variables. With a small sample size, the results of the ordination may be strongly influenced by outliers and fail to represent the reality of an ecological relationship. However, a smaller sample size may be adequate if there are strong reliable correlations between a distinct set of factors (Tabachnik and Fidell 1996). Although the small sample size could lead to misinterpretation of either the smallmouth bass or brook trout ordination, the associations between watershed and lake scale variables with fish THg concentrations are generally consistent with the weak relationships found for walleye and lake trout.

Water chemistry and nutrients, variables which are influenced by the vegetation, soil, and bedrock composition as well as anthropogenic activities within the watershed, can affect the bioaccumulation of mercury through the aquatic ecosystem. Lake chemistry was significantly linked to the physical attributes of the lake and waterbody catchment. Nutrients, reactive silicate, DOC, DIC, and base cations were associated with
one another and were higher in waterbody catchments with higher percentages of wetlands, proportion of the waterbody catchment classified as glacial and organic surficial material, and forest harvesting during the 1999-2000 and 2000-2009 decades (Figure 1.9).

Disturbances that alter groundwater flow and surface runoff can lead to the release of nutrients and DOC to receiving water bodies by overland flow and subsurface flow paths (Browne 2007; Kreutzweiser et al. 2008). The metabolism of oligotrophic boreal lakes is highly dependant on allochthonous supplies of nutrients and DOC from the watershed. The origin of DOC in lake water is primarily allochthonous at concentrations $<10 \mathrm{mg} / \mathrm{L}$ (Driscoll et al. 1995; Garcia and Carignan 1999). Thus, the low concentrations of DOC $(7.69 \pm 3.74 \mathrm{mg} / \mathrm{L})$ in these study lakes would suggest lakes are largely influenced by allochthonous inputs from the catchments.

The results of this study have shown that fish mercury concentrations were positively correlated with DOC concentrations (and negatively correlated to secchi depth) for all species of fish (Figure 1.10). These results are consistent with other studies by Schetagne and Verdon (1999), Garcia and Carignan (2000), Driscoll et al. (2007), and Simonin et al. (2008). Previous studies have reported conflicting results concerning the relationship between DOC and fish THg accumulation. Numerous studies have shown a positive correlation between lake water DOC and fish species THg concentration (McMurty et al. 1989; Wren et al. 1991; Garcia and Carignan 2000; Rencz et al. 2003; Belger and Forsberg 2006; Driscoll et al. 2007). In contrast, Grieb et al. (1990), Snodgrass et al. (2000) and Greenfield et al. (2001) documented a negative relationship between DOC and several different fish species. Finally, Simonin et al. (2008) found no association between DOC and yellow perch or bass THg accumulation. The biochemistry of DOC in each lake may be variable in terms of quality or quantity of DOC and mixed results could be explained by the influence of DOC on differences in mercury speciation, solubility, mobility and toxicity (Ravichandran 2004). However, dissolved organic carbon is likely an important vector for mercury transport from the waterbody catchment to the lakes in this study as well as an important determinant of mercury bioavailability.

Lake colour and DOC concentration are both functions of the wetland influence on the lake (D'Arcy and Carignan 1997). The DOC-mediated transport of mercury
species from the catchment is likely partially responsible for the positive correlation between percentage of wetlands and mercury in lake inflows which may indirectly lead to an increase in mercury bioavailability at the base of the food web and subsequent bioaccumulation in fish and wildlife (Driscoll et al. 2005). Much higher mercury levels have been found in fish from coloured lakes that received greater inputs from wetlands (Rudd 1995). In this study, a significant positive relationship was found between DOC concentrations in lake water and the percentage of wetlands in the waterbody catchment (Figure 1.11: a). Although wetlands are important sources of MeHg to boreal lakes, a high amount of variability exists for the relationship between DOC concentrations and associated wetland area. The type of wetland influences differences in biogeochemical processes and the source strength of MeHg yields to the lake (St. Louis et al. 1996). Additionally, the degree of connectivity between the wetland and the lake is also influenced by year to year variability in water yields (St. Louis et al. 1996). Wetland type, annual water yield, and hydrological connectivity of wetlands associated with each lake were not measured in the current study, consequently limiting our understanding of wetland influence on water chemistry.

Wetlands are not the only important source of DOC and MeHg to lakes. Although the results of this study showed DOC concentrations in lake water were not significantly correlated with recent harvesting disturbance (Figure 1.11: b), previous research has shown higher DOC loadings in watersheds that have been logged compared with those disturbed by fire (Lamontagne et al. 2000; Carignan et al. 2000). Large quantities of easily leached or decomposed organic material remaining after forest harvesting can increase the DOC concentration in lakes. Results from the Gouin Reservoir in HauteMaurice, Quebec showed dissolved organic carbon concentrations three-fold higher in cut lakes than in reference or burnt lakes (Carignan et al. 2000). Fresh DOC derived from harvesting disturbance may be less coloured than humic DOC derived from soil horizons (Carignan et al. 2000). Hence, variations in DOC structure and dissolved ions between harvested and non-harvested watersheds could lead to differences in the biogeochemical reactions involved with organic and inorganic mercury (O'Driscoll et al. 2005).

Lake productivity and nutrient inputs may also be important for mercury bioaccumulation processes. Overall, nutrients had a weak positive influence on fish THg
mercury concentrations (Figure 1.12). This weak relationship is supported by findings of Hayer et al. (2011) that water quality attributes such as nutrients are poor predictors of mercury concentrations in fish. Following forest harvesting disturbance, nitrogen mineralization and nitrification often increase resulting in increased nitrogen availability and exports to receiving waters (Kreutzweiser et al. 2008). Phosphorus undergoes similar processes and responses and may increase by a smaller degree than nitrogen (Kreutzweiser et al. 2008). Subsequent changes in primary productivity as a result of nutrient inputs may alter food web interactions by changing the abundance of primary consumers, thus influencing bioaccumulation of mercury in the food web (Planas et al. 2000).

The range of $\mathrm{pH}, 5.9$ to 8.6 , for my study lakes was within the range found in lakes in the north-eastern United States by where pH ranged from 5.0 to 9.1 (Greenfield et al. 2001; Simonin et al. 2008). The relationship between pH and fish mercury levels is typically negative across a wide range of lake types and species (Suns and Hitchin 1990; Wren et al. 1991; Bodaly et al. 1993; Scheuhammer and Graham 1999; Garcia and Carignan 2000; Greenfield et al. 2001; Essington and Houser 2003; Burgess and Hobson 2006; Simonin et al. 2008; Scudder et al. 2009). However, the present study did not support the theory that a lower pH increases the bioavailability of mercury thereby making more mercury available for bioaccumulation for the different species of fish analysed. Only walleye lakes showed a significant negative correlation between pH and walleye THg concentrations $(\mathrm{r}=-0.250, \mathrm{p}<0.01)$. Although the pH of lake water has been used as an important predictor of mercury levels in fish at the lanscape scale (Greenfield et al. 2001), many inconsistencies exist in the literature which suggests a significant degree of interaction among lake water pH and other confounding variables (Watras et al. 1998; Sonesten 2003). It is plausible that the observed relationship between methylmercury and lake pH is a result of the covariance between lake water colour and productivity (Meili 1994). Thus, slower growth of fish in dystrophic lakes with high concentration of humic substances may also be attributed to the limited productivity in darkly stained waters that have low pH , low light, and low oxygen concentrations.

The results of this study found that sulfate concentrations in lake water were not correlated to standardized mercury concentrations in fish tissue, comparable to research
by Simonin et al. (2008). The range of sulfate concentrations in water chemistry of my study lakes was relatively small, with only two lakes north of Elliot Lake having elevated sulfate concentrations (Quirke Lake: $48.4 \mathrm{mg} / \mathrm{L}$ sulfate, and Whiskey Lake: $36.4 \mathrm{mg} / \mathrm{L}$ sulfate) due to the presence of mining activity (Stanrock Mine). Sulfate availability has been shown to influence inorganic Hg bioavailability and microbial activity related to methylation of mercury (Gilmour et al. 1992; Heyes et al. 2000). Studies have shown a positive relationship between sulfate concentration and mercury concentrations in surface water (Gilmour et al. 1998; Wiener et al. 2006), periphyton (Desrosiers et al. 2006), zooplankton (Garcia et al. 2007), and northern pike (Garcia and Carignan 2000). However, finding a relationship between fish THg and surface water sulfate concentrations is difficult as sulfate reduction and bioaccumulation are two co-occurring processes.

The type and amount of dissolved ions in lake water will either aid or inhibit the methylation of mercury (Gabriel and Williamson 2004). Increases in water hardness as measured by dissolved ions (conductivity, $\mathrm{Ca}, \mathrm{Mg}, \mathrm{Na}$, and K ) could possibly reduce the bioavailabilty of neutral species of mercury (e.g., $\mathrm{Hg}(\mathrm{HS})_{2}, \mathrm{HgCl}_{2}, \mathrm{Hg}(\mathrm{OH})_{2}, \mathrm{HgS}$ ) that are important in methylation (Benoit et al. 1999; Kelly et al. 2003; Gabriel et al. 2009). Previous research has shown the acid neutralizing capacity (ANC) and concentrations of calcium, magnesium, and potassium base cations in the water were highly negatively correlated with mercury concentration in smallmouth bass, largemouth bass, walleye and yellow perch (Grieb et al. 1990; Spry and Wiener 1991; Simonin et al. 2008). Also, Sonesten (2003) found a negative relationship between dissolved ions and the mercury concentration in perch. Cations such as $\mathrm{Ca}^{2+}$ and $\mathrm{Mg}^{2+}$ released and exported to receiving waters after forest harvesting may coagulate and increase the precipitation of chelated humic substances thereby decreasing the bioavailability of mercury (Sonesten 2003). However, base cation concentrations were not significantly correlated to standardized mercury concentrations in any fish species in the lakes analysed in this study.

Compared to previous research, the spring water chemistry measurements used in this study were weakly correlated to mercury concentrations in fish. The inherent variability in water chemistry measurements (i.e. not measured on fine enough time or spatial scales) and the complex interactions between water chemistry variables and
methylation rates and bioaccumulation are reasons why this may be the case. Furthermore, sampling lake chemistry during dry or wet years may misrepresent the true associations between lake chemistry variables and mercury concentrations in piscivorous fish. In order to draw inferences on the relationships between lake chemistry and mercury concentrations in piscivorous fish, water chemistry should be sampled during the different seasons and over multiple years. Similarly, the average decadal weather conditions were measured on a coarse temporal scale. The average annual weather conditions as well as specific conditions occurring during each summer period should be considered in studies evaluating changes in watershed hydrology and mercury biogeochemistry as suggested by St. Louis et al. (1996).

The studies by Garcia and Carignan $(1999,2000,2005)$ are amongst the few studies that have evaluated the effects of forest harvesting and fire disturbance on mercury in aquatic biota of boreal forest ecosystems. Contrary to my predictions based on these studies I did not find significant associations between disturbance as percentage area of waterbody catchment and water chemistry or fish mercury concentrations (Figure 1.14Figure 1.17). However, lakes with fish having standardized concentrations $<0.5 \mathrm{ppm}$ w.w THg had consistently lower amounts of forest harvesting and natural disturbance within their waterbody catchments. The average percentage of the waterbody catchment affected by forest harvesting increased across the categories of contamination for walleye, northern pike, lake trout, and smallmouth bass. This suggests that forest harvesting may be one of many contributing factors responsible for the elevated mercury concentrations in certain species. Although lakes in this study varied with respect to lake size and catchment scale influences, a detailed study of small lakes which are likely the most sensitive may show differences in the response of fish mercury concentrations to catchment scale influences. Compared to the small headwater lakes considered in the studies by Garcia and Carignan (2000, 2005), the lakes in my study varied with respect to catchment scale characteristics as well as across a larger spatial scale. Differences in scale between studies may have influenced differences in the strength of waterbody catchment scale influences on mercury concentrations in piscivorous fish.

Similar results were found by Rask et al. (1998); the limnological response to clearcutting within the waterbody was modest. Moreover, the area disturbed by clear-
cutting may have a variable influence on the associated waterbody depending on the duration and areal extent of the disturbance impact, the intensity of mechanical site preparation, the extent of tree removal, and the pre- and post-logging treatment of the site. The connection between the lake and the disturbed area may also vary due to changes in hydrology (water table elevations and subsurface flow paths). Since the upland soils are only occasionally inundated by water, surface runoff is typically only generated in close connection to a waterbody. Yet, much of the mercury from disturbed watersheds is transported during storm events and is associated with high loads of soilderived suspended sediment (Engstrom et al. 2007). The magnitude of the forestry impacts may vary with position in the waterbody catchment but the intensity of the landwater linkage is generally the most intense near a body of water and decreases with the distance from the water body (Steedman et al. p. 59 in Gunn et al. 2003).

Forest harvesting has attracted international attention from the scientific community as a potentially significant driver in mercury contamination of aquatic ecosystems (Bishop et al. 2009). However, my study was not able to support this concept. Water chemistry responses to logging are highly variable and often site specific (Kreutzweiser et al. 2008). The probability and magnitude of logging impacts on soil nutrient cycling and exports in boreal forest watersheds is dependent on many factors such as soil type, stand and site conditions, hydrological connectivity, post-logging weather patterns, and type and timing of harvest activities (Kreutzweiser et al. 2008). Logging can change the hydrologic cycle of a watershed, increasing the total runoff and influx of nutrients, minerals, trace metals, and organic matter to the associated waterbody. Since the aquatic response to watershed disturbance was likely site specific it was difficult across a large landscape to connect mercury concentrations in fish to forest harvesting disturbance. There may have been differences in the sensitivity of the lakes included in this study towards forest harvesting disturbance within the waterbody catchment. The response of disturbed ecosystems to increased terrestrial inputs and within lake cycling of mercury may vary on a lake by lake basis. In future work, the influence of certain physical scale characteristics, such as forest harvesting, should be considered for lakes that are of similar waterbody catchment types.

Numerous studies have shown a significant positive relationship between associated wetlands and fish THg concentrations (Rudd 1995; Shanley et al. 2005; Castro et al. 2007; Simonin et al. 2008). Rypel (2010) found mercury concentrations in (bluegill [Lepomis macrochirus], largemouth bass [Micropterus salmoides], northern pike, walleye, and muskellunge [Esox masquinongy]) were significantly and positively related to the wetland area index. For my lakes the percentage area of the waterbody catchment covered by wetlands did not show a significant relationship with fish mercury concentrations for any species nor was a trend observed across the different lakes categorized by level of contamination. The lack of relationship between fish mercury concentrations and wetland percentage could be due to the lake/watershed-wetland size relationship. Large lakes may dilute the effects of wetland influence. Moreover, the highly variable influence of wetlands as sources of MeHg to associated waterbodies is related to differences in the internal hydrology of the wetland, the water yield of the catchment, the hydrological connectivity and the percentage of wetland areas within a catchment (St. Louis et al. 1996; Harris et al. 2007). The strength of the wetland area as a source of MeHg to the lake and contributing factor to mercury in fish would be better understood if differences in wetland hydrology and the annual water yield were determined.

Interestingly, walleye and lake trout lakes with higher amounts of wetlands and forest harvesting disturbance in their watersheds shared similarities in water chemistry characteristics (Figure 1.4 and Figure 1.6). Watersheds with greater amounts of wetlands are at higher risk of logging impacts on nutrient export and receiving water chemistry (Kreutzweiser et al. 2008). However, it is possible that the relatively low sample size makes it difficult to distinguish the confounding watershed interactions and the study design did not allow for sites to be selected based on separate wetland or disturbance characteristics.

Overall, my results were consistent with previous research on the affect of lake size on mercury concentrations in fish. Small lakes (size bin 1: $<100 \mathrm{ha}=1 \mathrm{~km}^{2}$ ) tended to show higher fish mercury concentrations compared to larger lakes for northern pike, lake trout, and smallmouth bass. No trend in the relationship between lake size and THg concentration was observed for walleye or brook trout populations. There are several
ecological explanations for these results. Mercury concentrations tended to be higher in fish of smaller lakes than larger lakes in the Mackenzie River Basin as a probable consequence of higher summer epilimnion temperatures (Evans et al. 2005). The effect of lake size on mercury concentration may be stronger for some fish species than others, in part because of differences in their habitat use within a lake and growth rates as a function of lake size (Evans et al. 2005). Mercury concentrations were predicted to exceed the 0.5 ppm threshold guideline for commercial sale of fish in 600 mm lake trout living in lakes smaller than $6500 \mathrm{ha}, 450 \mathrm{~mm}$ walleye living in lakes smaller than 2000 ha, and 600 mm northern pike living in lakes less than 100 ha (Evans et al. 2005). Lakes showed a strong negative relationship between mercury concentrations of length-adjusted fish and lake surface area, especially for lake trout $\left(r^{2}=0.71\right)$ (Evans et al. 2005). The optimal thermal range and dissolved oxygen habitat can influence growth rates of lake trout (Evans et al. 2005). The mercury concentrations of walleye and northern pike are less likely to be correlated with lake size because they primarily inhabit littoral habitat which does not expand as appreciably with increasing lake size (Evans et al. 2005).

Aside from habitat, lake size has been shown to be negatively correlated with mercury concentrations due to higher epilimnion temperatures and presumably higher ratios of methylation (Bodaly et al. 1993). Smaller lakes are generally shallower and respond more quickly to changes in atmospheric temperature. The greater variation in surface water temperature of small lakes could lead to higher rates of methylation relative to demethylation (Bodaly et al. 1993). As lake size increases the pelagic zone becomes an increasingly large proportion of the lake area or volume and efficiently dilutes and cools surface water inflows from the watershed during the summer months (Evans et al. 2005).

Watershed characteristics are also likely to exert a relatively greater influence on small lakes (Suns and Hitchin 1990; Bodaly et al. 1993). The higher mercury concentrations in fish in small lakes could be a result of a greater influence from allochthonous inputs of organic matter from the watershed (Greenfield et al. 2001). Differences in study lake size may be one of the reasons my results were not consistent with those of Garcia and Carignan $(2000,2005)$ who found that the ratio of clear-cut area to lake area was significantly related to mercury concentrations in fish. Their study lakes
from the Réservoir Gouin in Haute-Mauricie, Québec ranged from 20 to 230 ha with watershed areas ranging from 50 to 1970 ha whereas my study lakes had an average surface area of 1739 ha and an average waterbody catchment of 5362 ha. Additionally, I observed no significant relationship between lake surface area and mercury concentrations in fish. My results are consistent with a study of 161 lakes by Rypel (2010) which found no significant relationship between lake area and mercury concentrations in the five species of piscivorous fish. Differences in lake morphometries, drainage ratios and water renewal times may explain the different impacts of major watershed perturbations, such as forest harvesting, on the water quality and aquatic biota (Carignan and Steedman 2000).

Since MeHg is biomagnified through the food chain, among lake variability in THg for a given species can be due to inter-lake differences in trophic position (Cabana and Rasmussen 1994). Muscle concentrations of mercury are highly related to the trophic position of fish (Kidd et al. 1995; Sharma et al. 2008). Fish trophic position explained more variation in fish mercury concentrations than watershed and lake characteristics (Garcia and Carignan 2005). Accounting for trophic position is particularly useful for among-lake comparisons of omnivorous fish, such as lake trout, which have highly variable methylmercury concentrations even within a single life stage due to inter-lake differences in trophic position (Wiener et al. 2003).

When comparing fish mercury concentrations from different lakes, it is important to take lake trophic position into account in combination with lake and catchment characteristics (Cabana and Rasmussen 1994; Vander Zanden and Rasmussen 1996; Garcia and Carignan 2005). As trophic position increases, so does the mercury bioaccumulation in piscivorous fishes (Cabana and Rasmussen 1994; Kidd et al. 1995). Trophic position explained most of the variability in mercury concentrations of piscivorous fish species standardized to an average length (Garcia and Carignan 2005). In addition, Garcia and Carignan (2005) were able to determine the relationship between fish mercury concentrations and amount of watershed disturbance once the fish were normalized to trophic position. Evaluating the effect of watershed catchment scale influences on mercury levels in fish from different lakes in my study was challenging without knowledge of the among-lake differences in trophic position. Although lake-to-
lake differences in fish mercury concentrations did not appear to be influenced by forest harvesting disturbance, there may have been a different relationship observed if mercury concentrations in fish were standardized to length as well as the lake specific $\delta^{15} \mathrm{~N}$ defined trophic position. This approach would have allowed for a direct comparison of trends in mercury concentrations in fish of lakes having different trophic structure and degrees of watershed perturbation (Garcia and Carignan 2005).

## Conclusion

Mercury concentrations in fish of neighbouring lakes are known to vary because of differences in internal MeHg production within a lake, differences in MeHg inputs from dissimilar types of watersheds surrounding lakes, and/or differences in the bioavailability and trophic transfer of methylated mercury. Fish mercury concentrations varied greatly among the different lakes in this study and showed weak associations with waterbody catchment and lake chemistry characteristics. This study does not support the hypothesis that elevated fish mercury concentrations are associated with lakes having recent forest harvesting disturbance within the catchment. Future work should continue to evaluate differences in lake sensitivity towards forest harvesting disturbance at a finer spatial scale. Although mercury concentrations in piscivorous fish of these study lakes did not appear to be associated with forest harvesting disturbance, the lakes may have had differences in their sensitivity to forest harvesting disturbance. Even if forest harvesting increased MeHg bioavailability within a lake, there are many dynamic processes that occur within the environment that lead to the elevated concentrations found in piscivorous fish. The association between forest harvesting and elevated mercury concentrations in piscivorous fish may have been masked by numerous biological scale factors that also influence mercury cycling within the food web. This finding may support other research that suggests that biological considerations, such as trophic structure, may exert a greater role on the concentration of mercury in piscivorous fish.

## 2. Walleye Mercury Relationships with Population Characteristics

## Introduction

Elevated methylmercury burdens in piscivorous fish of freshwater lakes is largely a consequence of biological controls that affect the bioaccumulation of Hg (Watras et al. 1998; Simoneau et al. 2005; McIntyre and Beauchamp 2007; Lavigne et al. 2010). Included among the suite of biological factors affecting mercury concentration are food web structure, trophic status, fish population structure, growth rates of individual fish, and physiological controls on uptake (Grieb et al. 1990; Wiener et al. 2003; McIntyre and Beauchamp 2007; Munthe et al. 2007; Gabriel et al. 2009). Biological controls are often not considered in studies attempting to explain contaminant levels in biota due to the difficulty in accurately quantifying biological characteristics but are hypothesized to explain a fraction of the between-lake variability in THg concentrations in fish (Vander Zanden and Rasmussen 1996). Although many physical, chemical, and biological scale factors are known to influence mercury concentrations in piscivorous fish, investigations that consider the relative importance of these scales are currently lacking.

The dynamics of the food web is an important biophysical control on methylmercury bioaccumulation and biomagnification by wildlife (Munthe et al. 2007). The bioaccumulation of mercury ultimately originates at the lowest level of the food web and variations in the standing biomass, productivity rate, or composition of the lower trophic levels may cascade through the food web and result in alterations to the bioaccumulation rate and levels of mercury contamination in higher trophic level species among different lakes (Allen et al. 2005). Methylmercury produced in lake sediments can be directly incorporated into the benthic food web by periphyton (Desrosiers et al. 2006; Bell and Scudder 2007) and benthic invertebrates (Wong et al. 1997) or may enter the water column and become incorporated into pelagic food webs by microseston (phytoplankton, bacterioplankton, and cellular debris) and zooplankton uptake (Watras et al. 1998; Munthe et al. 2007). Once fish become large enough to shift their diet from planktivory to benthivory and eventually piscivory the mercury accumulation rate accelerates abruptly (Power et al. 2002; Wiener et al. 2003). Furthermore, the length of the
underlying food chain significantly affects the concentration of mercury in top predator species of fish (Cabana et al. 1994).

Growth rates have been generally overlooked, compared to other factors such as length (Schetagne and Verdon 1999) or trophic level (Tremblay et al. 1998), in studies attempting to predict fish mercury levels in specific lake environments (Lavigne et al. 2010). The influence of growth rate on fish mercury levels has been shown to supersede the influence of all other environmental factors including point source pollution from mine tailings within the immediate vicinity of study lakes (Simoneau et al. 2005).

Decreased fish abundance from intensive fishing may lead to increased growth rates of the remaining fish, due to decreased inter- and intra-specific competition, resulting in more efficient growth following fishing. Verta (1990) measured growth rates before and after an intensive fishing operation in which half of the fish biomass, including piscivorous fish, was removed from a small (17 ha) remote lake in Finland. Northern pike growth rates doubled and mercury concentrations were significantly decreased after the intensive fishing operation. The decrease in mercury concentrations in fish was hypothesized to be a result of a couple different scenarios including increased growth following reduced competition for food (Verta 1990). Manipulations of fish growth were proposed as a means to manage Hg contamination in fisheries (Verta 1990).

In a northern Quebec intensive fishing experiment on two lakes Surette et al. (2005) found decreased walleye mercury concentrations corresponded to increased growth of fish. The decline in fish mercury was unrelated to changes in fish diet, structural alterations of the food web, reductions of methylmercury in forage fish, or reductions in the methylmercury content of the lake by fish removal (Surette et al. 2005). Similar results were found for a study in Norway, where significant declines in total mercury were observed in northern pike following intensive fishing in a 120 ha lake (Sharma et al. 2008). Larger fish that grow faster have had lower concentrations of Hg compared to smaller slower growing fish due to somatic growth dilution (SGD) whereby fish accumulate more biomass relative to Hg (Ward et al. 2010). Studies have shown that SGD is a factor influencing variability in Hg concentrations in fish since populations of fast growing fish have proportionately greater gains in biomass relative to the amount of mercury bioaccumulated in somatic cells than slow growing fish (Simoneau et al. 2005;

Lavigne et al. 2010). Among lake variation in activity costs of foraging and predator avoidance influences contaminant bioenergetics in freshwater fish (Rennie et al. 2005). Active fish that allocate energy into survival (i.e. predator avoidance) rather than growth or reproduction have been observed to grow slower resulting in higher mercury concentrations in fish due to lower growth efficiency (Rennie et al. 2005). Moreover, if food availability is limited there are greater costs associated with obtaining energy for growth and reproduction (Rennie et al. 2005). Thus, fish bioenergetic processes that influence fish growth are indirectly linked to mercury bioaccumulation.

This study examined the relationship between growth rates and mercury concentrations in walleye from a subset of lakes in northern Ontario. The specific objectives of this study were to:

1) Determine if mercury concentrations are related to growth rates of walleye. If growth rate influences mercury bioaccumulation in piscivorous fish, then slower growing walleye would have elevated fish mercury concentrations compared to faster growing walleye as a result of higher energetic costs to increase in body size.
2) Determine if growth rate in walleye is related to abundance of individuals in a lake.

If the density of walleye individuals is higher in certain lakes than others, then I would expect that growth rates would be slower as a result of increased competition.

## Methods

Study lakes were chosen from those of the Ontario Ministry of Natural Resources (OMNR) Broad-Scale Fisheries Monitoring Program (OMNR 2009). The walleye lakes included in this analysis are a subset of lakes from Chapter 1 that also had information on fish age (analysis conducted by the Ontario Ministry of Natural Resources, Mann 2004). This study was limited to walleye for 99 lakes (summarized in Appendix E). Available sample sizes for lake trout, northern pike, smallmouth bass, and brook trout populations were insufficient to perform analysis because there were too few fish or too few lakes where ageing structures were collected.

An indicator of growth rate, age at standardized length, was used to determine the influence of growth on mercury concentrartions in walleye similar to methods used by Simoneau et al. 2005 and Lavigne et al. 2010. Since it was not feasible to calculate the growth rate of individual fish throughout their lifetime, this study involved one season of fish collection that represents different age-classes of fish. Several functions or models have been used to model the mean length or weight of fishes with age (Ogle 2011). The von Bertalanffy (VB) growth model provides a good description of somatic growth of mature fish (Lester et al. 2004). For each lake, the VB model (Equation 1) was used to fit the non-linear relationship between fish length and age for walleye individuals using the NCStats and Fisheries Stock Assessment (FSA) package in R (Ogle 2011; R 2011). The pattern of declining growth rate with age is based on the change in energy allocation from somatic growth to reproduction as the fish matures (Lester et al. 2004). Thus, the walleye growth rate proxy ( $\mathrm{Age}_{\mathrm{L} 500 \mathrm{~mm}}$ ) was calculated for a mature fish having a standard total length of 500 mm , which is assumed to be a mature size. Walleye in Ontario's inland lakes typically have reached maturity a total length of 500 mm . Separate studies of Ontario and Quebec lakes have shown the mean length when female walleye reach maturity is approximately $400-450 \mathrm{~mm}$ and the mean length for male fish to reach maturity is $324-350 \mathrm{~mm}$ (Morton 2006; Venturelli et al. 2010).

Equation 1. $L_{T}=L_{\infty}\left(1-\mathrm{e}^{-\mathrm{K}\left[t-t_{0}\right]}\right)$
Where:

- $\mathrm{L}_{\mathrm{T}}$ is the total length (mm) of fish at time t (years; which represents the fish age as
determined with ageing structures)
- $\mathrm{L}_{\infty}$ is the asymptotic length (mm)
- $K$ is the growth coefficient, and $t_{0}$ is the hypothetical fish age (years) at a length of 0 mm .

For each lake, the fit of the VB growth model was evaluated based on visual assessement of the VB growth trajectory, the plot of the model residuals, and the histogram of the residuals (Ogle 2012) (Appendix E: Table 1). The assumptions underlying nonlinear regression models of homoscedasticity and normally distributed measurement errors were validated by the plot of the model residuals and the histogram of the model residuals (Ogle 2012). Graphical procedures were sufficient to validate the model fit, but were supplemented by statistical tests (Ritz and Streibig 2008). Nonlinear model diagnostics included the lack of fit test, F-test, likelihood ratio test, and plot of residuals (Appendix E: Table E.2). However, the statistical tests used in assumption checking are hyper-sensitive (Ogle 2012). Fish were collected with a random sampling design and independence was ensured by lethal sampling which eliminated the chance for repeated measurements on the same fish. If the VB growth model failed to converge to fit the data, linear regression was used to describe the relationship between length and age for the fish population (Appendix E: Table E.3). Lakes were excluded from analysis if the walleye growth trajectory reached an asymptote before 500 mm total length (i.e. the maximum size of fish in the lake is less than 500 mm ) or if the Age $_{\text {L500mm }}$ was greater than the maximum age of fish sampled from the lake.

Walleye mercury concentrations ([THg] ${ }_{\text {L500 }} \mathrm{mm}$ ppm w.w) were calculated for each walleye population in the previous chapter for a standard fish of 500 mm total length using a power-series regression (refer to methods section in the previous chapter for details and Appendix D) (Gewurtz et al. 2011). The influence of growth on mercury bioaccumulation was evaluated by the relationship between total mercury concentration at the standard length $\left([\mathrm{THg}]_{\mathrm{L} 500 \mathrm{~mm}}\right.$, ) and the average growth rate $\left(\right.$ Age $\left._{\mathrm{L} 500 \mathrm{~mm}}\right)$ which was determined by linear regression analysis.

The relationship between Age $_{\mathrm{L} 500 \mathrm{~mm}}$ and $[\mathrm{THg}]_{\mathrm{L} 500 \mathrm{~mm}}$ concentration with the abundance of walleyes was evaluated with linear regression. A subset of 95 lakes with
population data were included in this analysis. A measure of walleye abundance was calculated as catch per unit effort (CPUE) by determining the average number of walleye caught in the North American (NA1) large mesh nets (stretch size 38, 51, 64, 76, 89, 102, $114,127 \mathrm{~mm}$ ) per unit effort. Effort for large mesh gill nets was calculated by a random sampling design based on surface area and depth strata to ensure equal efforts among all lakes (Sandstrom et al. 2011).

## Results

## Walleye Growth Rates

The age of walleye at the standard total length of 500 mm (Age $\mathrm{L}_{\mathrm{L} 500 \mathrm{~mm}}$ ) ranged from 3.44 years to 20.56 years suggesting that walleye growth rates are highly variable amongst lakes. Mature fish that take a long time to reach a standard total length of 500 mm tended to have higher THg concentrations than faster growing fish of other lakes; illustrated by the relationship between the growth rate ( Age $_{\text {L500mm }}$ ) and standardized mercury concentration ( $[\mathrm{THg}]_{\mathrm{L} 500 \mathrm{~mm}}$ ) for 99 walleye lakes (Figure 2.1; $\mathrm{r}^{2}=0.333, p<$ 0.001 ). Thus, mercury concentrations in walleye were typically higher in lakes with slower growing walleye compared to lakes with faster growing walleye.

Figure 2.1. The relationship between walleye growth rate ( $\mathrm{Age}_{\mathrm{L} 500 \mathrm{~mm}}$ ) and standard mercury concentrations ( $[\mathbf{T H g}]_{L 500 \mathrm{~mm}}$ ) for 99 lakes.

## Associations between Walleye Abundance and Growth Rates

Walleye standard mercury concentrations were not significantly associated with the density of walleye (Figure 2.2; $\mathrm{n}=95, \mathrm{r}^{2}=0.001, p=0.807$ ). However, the time required for walleye to grow to 500 mm ( $\mathrm{Age}_{\mathrm{L} 500 \mathrm{~mm}}$ ) was significantly positively related to the density of walleye (Figure 2.3; $\mathrm{n}=95, \mathrm{r}^{2}=0.136, p<0.0001$ ) indicating that walleye growth rates are lower in more dense populations.

Figure 2.2. The relationship between walleye density and walleye standardized total mercury concentration for 95 walleye lakes.

Figure 2.3. The relationship between walleye density and growth rate ( Age $_{\text {L500mm }}$ ) for 95 walleye lakes.

## Discussion

The results of this study suggest that the mercury concentrations of walleye are significantly influenced by growth rate with slower growing fish tending to have higher Hg levels (Figure 2.1). The positive relationship observed between standardized mercury levels and the age that fish reached 500 mm for the 99 walleye populations studied (Figure 2.1) was similar to the strong positive relationship between walleye standard mercury levels and age found by Simoneau et al. (2005) for 12 walleye populations (r $=0.92, \mathrm{p}<0.001$ ) and Lavigne et al. (2010) for 54 walleye populations $\left(\mathrm{r}^{2}=0.55, \mathrm{p}<0.001\right)$. The strong positive relationship between growth and mercury concentrations supports the conclusion of other studies that growth efficiency influences the process of mercury bioaccumulation by walleye (Simoneau et al. 2005; Lavigne et al. 2010; Ward et al. 2010).

Walleye growth rates are the by-product of an optimization process of energy allocation which is influenced at a fish community level. The growth rates of walleye were significantly affected by the walleye abundance (CPUE) (Figure 2.3). These results could suggest that slow growth rates and higher mercury concentrations in fish of certain lakes could be related to fish density in those lakes. Lakes with dense fish populations may exhibit reduced growth rates in fish causing fish that grow less efficiently to have higher tissue Hg concentrations relative to faster growing fish (Stafford and Haines 2001). Greater intra-specific competition for food sources exists in less intensely fished smaller lakes compared to larger lakes (Stafford and Haines 2001).

Slow growth rates of walleye found in certain lakes may be indicative of relatively low fishing pressures. Lakes that are less accessible or lakes with low fishing pressure relative to lake size may have old, slow growing fish with high mercury levels as a result of mercury bioaccumulation over a longer lifespan. Similar results were found in lakes of the Mackenzie River Basin (Evans et al. 2005) where fish populations tend to be dominated by older individuals where fishing pressure is low or nonexistent (Evans et al. 2005). Increased fishing pressure from sport-fishing or commercial fishing may remove older, larger fish from the population thereby reducing energy costs associated with predator avoidance and competition for food amongst the remaining fish. A sustainable amount of fishing pressure may influence fish bioenergetics and contaminant
accumulation by enhancing growth rates and subsequently decreasing the burden of contaminants in piscivorous fish. Although fishing pressure was not measured for the lakes in this study, it may be related to growth rates of piscivorous fish and should be considered in future work.

The growth rate is an integrative indicator of multiple environmental conditions and varies in the significance on its effect on fish THg concentrations (Lavigne et al. 2010). Environmental conditions that promote slow growth, such as low light, low temperature, and low nutrient concentrations, can affect bioaccumulation and biomagnification rates of mercury (Muir et al. 2001). The foraging efficiency of fish, such as walleye, that rely on sight for hunting is related to water turbidity (Abrahams and Kattenfeld 1997). Thus, environmental factors that influence growth rates are also likely responsible for the elevated mercury in walleye observed in smaller dystrophic lakes.

Growth rate is a reflection of the surrounding environment, including the climate and geography, which in turn affects fish metabolism, feeding ecology and lake productivity (Schindler 1995). However, because the lakes of this study were sampled across a broad region of Ontario at approximately the same latitude I do not expect that climate variability is a primary contributor to observed differences in growth rates. This conclusion is further supported by the results of Chapter 1 which showed climate had very little association with variability in lake characteristics. Often, fish of more northern regions are slower growing than those from lakes in central Canada (Colby and Nepszy 1981; Galarowicz and Wahl 2003). However, further examination of the environmental and biological parameters that control the growth of fish could provide insight to the causes of inter-lake differences in fish mercury concentrations.

The growth of walleye may also be negatively affected by the toxicological effects of mercury. Fish exposed to dietary methylmercury have shown loss of coordination, diminished swimming activity, starvation, reduced growth, impaired reproduction and mortality (Friedmann et al. 1996; Mahaffey 2006; Weis 2009; Sandheinrich and Wiener 2011). A review by Sandheinrich and Wiener (2011) concluded that adverse health effects such as altered behaviour, development, growth and reproduction are associated with mercury concentrations of 0.30 ppm w.w. or greater in freshwater fish. As the average mercury concentrations in fish exceeded this threshold for the majority of lakes
in this study, mercury is likely negatively impairing the growth of piscivorous fish to some degree. Future studies could examine the effects of mercury toxicity on fish growth to determine if a feedback mechanism between growth, toxicity, and mercury concentrations in fish exists.

## Conclusion

Walleye growth rates, which were highly variable among lakes, are able to explain a portion of the variability in mercury concentrations among lakes. The variability in mercury concentrations in walleye may be explained by differences in growth efficiency with respect to costs associated with obtaining and processing food. Abundance of individuals in a population may indirectly influence mercury concentrations in walleye by decreasing growth rates. As mercury bioaccumulation in fish is influenced by growth, further research would benefit from a better understanding the biological and environmental influences on growth. Further work could investigate the influence of fishing pressure on lake ecology and the link to bioenergetics and mercury bioaccumulation of piscivorous fish.

## 3. General Discussion and Conclusion

In Chapter 1, standardized THg concentrations were shown to differ by an order of magnitude or more between populations of fish in lakes across FMZs 4, 6, 7, 8, 10 and 11 in northern Ontario. No point source of mercury pollution existed for the vast majority of lakes in this study yet their piscivorous fish populations are highly contaminated with mercury and human consumption restrictions are advised. The variability in THg concentrations was not associated with forest harvesting nor many of the waterbody catchment or lake characteristics used as predictors of THg concentrations in fish in similar studies. For all species, higher THg concentrations in fish were associated with smaller, darkly stained dystrophic lakes. For all species, fish THg concentrations showed the strongest relationship with dissolved organic carbon concentrations in lake water.

Although the present study did not show significantly higher THg levels in piscivorous fish of lakes affected by clear-cutting, the disturbance may have altered the cycling of mercury in the watershed ecosystem resulting in an indirect influence on THg bioavailability and concentrations in lower trophic level biota. The lack of relationships between watershed and lake scale factors and THg concentrations in piscivorous fish could be due to the limitations of the available dataset, rather than a true absence of influence from factors such as forest harvesting disturbance or wetlands. Future attempts to relate landscape features with mercury in piscivorous fish of this region could focus on similar watershed/lake ecosystems with a greater range of disturbance area impacted by forest harvesting and fewer confounding factors.

Studies that attempt to evaluate the effects of forest harvesting would benefit from using a before-and-after design. However, my study would have likely been more useful in demonstrating watershed impacts on water chemistry and lower trophic level organisms. Studies which evaluate the spatial associations with THg contamination in piscivorous fish would benefit by considering characteristics such as trophic structure and growth rates.

In Chapter 2, the variability in THg concentrations of walleye was partially explained by differences in growth rates. Thus, biological characteristics of the fish population and aquatic community likely exert a strong influence on the high levels of

THg found in piscivorous fish. Understanding the complex relationships between landscape, limnological, and ecological factors that synergistically affect the mercury cycle will subsequently lead to a better understanding of THg concentrations that bioaccumulate and biomagnify to dangerously high levels in piscivorous fish. This study illustrated the difficulty of determining the associations between mercury concentrations in fish across a broad landscape, suggesting mercury concentrations in fish vary on a lake by lake basis due to differences in the relative importance of watershed, lake and biological scale factors. Although mercury concentrations in piscivorous fish were weakly associated with characteristics of the waterbody catchment, further investigation of the importance of scale on lake sensitivity to disturbances is required. Future work could consider additional analysis of lake ecosystems that have similar population and community ecology in order to further evaluate the importance of catchment scale characteristics.

Further research of mercury sensitive ecosystems across northern Ontario is required as much of the boreal forest is a likely target for development (i.e. mining) in the near future. The development of new road networks will likely increase sport-fishing opportunities in once remote lakes which may have elevated concentrations of mercury in the fish. Increased fishing pressures may alter both fish populations and community dynamics, thus indirectly affecting how mercury is bioaccumulated and biomagnified. Therefore, due to the dynamics of lake ecosystems, constant monitoring of mercury contaminant levels in fish of Ontario's lakes is recommended.

# Appendix B. Software Used, Data Sources, and Waterbody Catchment Variables 

Software Used:

- ArcGIS (version 9.3.1) ${ }^{2}$
- Microsoft Excel 2003
- Microsoft Access 2003
- R (version 2.13.1) ${ }^{3}$ and vegan package ${ }^{4}$
- IBM SPSS Statistics $19^{5}$
- Historical Climate Analysis Tool ${ }^{6}$
- NCStats and FSA package- Fisheries Stock Assessment Methods Version 0.2-6 ${ }^{7}$

Data from the Ontario Geospatial Data Exchange (OGDE) Land Information Ontario (LIO) Used:

- Digital Elevation Model (version. 2.0.0) ${ }^{8}$
- Enhanced Flow Direction Grids for Zones 15, 16n, 16se, 17ns, 17nn
- Provincial Land Cover 2000-27 Classes (PLC2000)
- Bedrock Geology of Ontario (1:250,000), Ontario Geological Survey Data
- Ontario Hydrographic Network: Waterbody
- Water Virtual Flow - Seamless Provincial Data Set
- Surficial Geology from the digitized version of the Northern Ontario Engineering Geology Terrain Study (NOEGTS)
- Wetland Interim
- Natural Resources Values Information System (NRVIS) 2009 Roads layer

[^2]Forest harvesting and natural disturbance data were available from the forensic forestry layer provided by Larry Watkins, Forest Analyst for the Forest Evaluations and Standards Section of the Ministry of Natural Resources. The forensic forestry layers were created from combining Ontario Forest Resources Information, Silvicultural Effectiveness Monitoring, Provincial fire, Provincial blowdown, and Annual Report GIS data.

Data from Larry Watkins, Forest Analyst for the Forest Evaluations and Standards Section, Forests Branch of the Ministry of Natural Resources (Sault Ste. Marie, Ontario).

- Forensic Forestry layers: yrdep_90 (1990-1999) and yrdep_00 (2000-2009)
- Harvesting Data from Annual Report 2002-2009
- Provincial Depletion Blowdown and Fire 2000-2009

Table B.1. Waterbody Catchment Area Characteristics per Lake (Harv = forest harvesting disturbance, Dist = natural disturbance).

| Lake Name | Lake Area (\%) | Wetland Area (\%) | $\begin{aligned} & \text { Harv1999-2000 } \\ & (\%) \end{aligned}$ | $\begin{aligned} & \text { Harv2000-2009 } \\ & (\%) \end{aligned}$ | $\begin{aligned} & \text { Dist1999-2000 } \\ & (\%) \end{aligned}$ | $\begin{aligned} & \text { Dist2000-2009 } \\ & (\%) \end{aligned}$ | Road Density km ha |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Addie Lake | 12.9 | 2.1 | 0.0 | 18.7 | 1.3 | 0.0 | 0.0062 |

If year sampled $=0$, then water chemistry was not sampled for this lake.

## Appendix D. Fish Standardized Total Mercury Concentrations

The standard total length according to species (Table 1) was determined by evaluating the population averages for all species (Fig. 1) as well as the standard used by the Ministry of the Environment (MOE) (Gewurtz et al. 2010). Standards for brook trout and smallmouth base were based on the data collected from the lakes of this study as no standard was available from the MOE. The standardized mercury concentrations for each species from individual lakes are presented in Table 2.

Table D.1. Fish Names and Standard Lengths

| Species Common Name <br> (MNR CODE) | Species Scientific Name | Standard Length (mm) |
| :--- | :--- | :--- |
| Walleye (SPC 334) | Sander vitreus | 500 |
| Northern Pike (SPC 131) | Esox lucius | 650 |
| Lake Trout (SPC 081) | Salvelinus namaycush | 600 |
| Brook Trout (SPC 080) | Salvelinus fontinalis | 300 |
| Smallmouth Bass (SPC 316) | Micropterus dolomieu | 400 |

Figure D.1.Total Lengths of Sampled Fish according to Species. The horizontal black line represents the median, the boxes indicate the inter-quartile range (IQR) and the whiskers represent 1.5 times the $I Q R$ from the first and third quartile, hollow circles represent data outside of the (Q1-1.5* IQR, $\mathrm{Q} 3+1.5 * \mathrm{IQR}$ ). The mean is represented by the black triangle and the number of samples ( n ) represents the number of lakes in that category.

Table D.2. Standard Mercury Levels according to Lake and Species determined for a standard length by power regression analysis

## Appendix E. Standard Age Calculations for Walleye

The standard age estimates (Age ${ }_{\text {Lstd }}$ ) of walleye at a total length of 500 mm was calculated for 99 lakes (Table 1). Overall, the non-linear model assumptions were adequately met with the Von Bertalanffy Growth curve. The fit of the nonlinear model was evaluated by determining certain statistical parameters; for most fish populations, the model appeared to fit the data appropriately with slight heteroscedasticity and approximately normal residuals (Table 2). Linear regression analysis was used to estimate Age $_{\text {L500mm }}$ for 9 lakes where the Von Bertalanffy (VB) growth model did not converge to fit the data (Table 3).

Table E.1. Walleye age at standard total length of 500 mm (Age Lstd ) for each lake and $\mathbf{9 5 \%}$ upper and lower confidence intervals. Linear regression analysis was used for 9 lakes.
